Papers.

January.

General, Physical and Inorganic.

Ira Remsen: The Development of Chemical Research in America.....	1
T. W. Richards and F. O. Anderegg: The Inclusion of Electrolyte by the Deposit in the Silver Voltameter.....	7
Hugh Stott Taylor: The Interaction of Hydrogen and Chlorine under the Influence of Alpha Particles.....	24
Alexander Smith and Robert H. Lombard: The Densities and Degrees of Dissociation of the Saturated Vapors of the Ammonium Halides, and the Related Thermal Data.....	38
G. A. Linhart: On the Rate of Reduction of Mercuric Chloride by Sodium Formate.....	70
George McPhail Smith: The Effect upon their Solution Tensions of Dissolving the Alkali and Alkali Earth Metals in Mercury, and the Constitution of such Solutions.....	76
Theodore W. Richards and Thorbergur Thorvaldson: A New Thermochemical Method for Subdividing Accurately a Given Interval on the Thermometer Scale.....	81
Edward Ellsworth Marbaker: The Separation of Tungsten from Molybdenum..	86
Theodore W. Richards and Charles R. Hoover: The Molecular Weight of Sodium Sulfate and the Atomic Weight of Carbon Referred to Silver and Bromine...	95
Theodore William Richards and Charles R. Hoover: The Molecular Weight of Sodium Sulfate and the Atomic Weight of Sulfur.....	108
Gregory Paul Baxter and Miner Louis Hartmann: A Revision of the Atomic Weight of Cadmium.....	113
L. M. Dennis and B. J. Lemon: The Electrolysis of Solutions of the Rare Earths.	131
Merle Randall and F. Russell v. Bichowsky: Vacuum and Pressure Stopcocks...	137
Notes: Blast-Lamp for Natural Gas; A Modified Kipp Generator; An Improved Heating Apparatus for Maintaining Constant Temperature in Work with Polarimeters and Refractometers; Measurement of the Vapor Pressures of Solutions.....	144

Organic and Biological.

James Kendall and Willis A. Gibbons: The Addition Compounds of Aldehydes and Ketones with Organic Acids.....	149
Treat B. Johnson and Edward F. Kohmann: 3-Nitro-4-hydroxycinnamic Acid and its Methyl Ether.....	162
Alfred E. Sherndal: On the Blue Hydrocarbon Occurring in Some Essential Oils.	167
Treat B. Johnson and Sidney E. Hadley: Researches on Hydantoins. XXIX. Geometrical Isomerism in the Hydantoin Series.....	171
Treat B. Johnson and Howard W. Haggard: Researches on Pyrimidines. LXXIII. Alkylation of 2-Mercaptopyrimidines.....	177
E. W. Esslinger and S. F. Acree: On 1-Phenyl-4,5-dihydro-5-oxy-3-triazolylsulfonic Acid and 1-Phenyl-4,5-dihydro-5-oxy-3-triazolylmethylsulfone.....	183
William A. Noyes and Ralph S. Potter: The Valence of Nitrogen in Ammonium Salts.....	189
T. B. Aldrich: On the Presence of Histidine-like Substances in the Pituitary Gland (Posterior Lobe).....	203

Robert A. Hall: Tri-ammonium Citrate.....	208
K. George Falk and K. Sugiura: Studies on Enzyme Action. XII. The Esterase and Lipase of Castor Beans.....	217
Thos. G. Thompson: The Total Amino Nitrogen in the Seedlings of the Alaska Pea.....	230
New Books: Landolt-Börnstein Physikalisch-Chemische Tabellen; Notes on Elementary Inorganic Chemistry; Manual of Quantitative Chemical Analysis; Principles of Quantitative Analysis. An Introductory Course; Monographs on Inorganic and Physical Chemistry; Outlines of Organic Chemistry; A Study of Foods.....	236

February.

General, Physical and Inorganic.

Grinnell Jones and Miner Louis Hartmann: A Study of the System: Water, Potassium Iodide and Iodine at Zero Degrees.....	241
G. A. Linhart: On the Association of Mercuric Chloride in Water Solution.....	258
J. M. Nelson and K. George Falk: The Electron Conception of Valence. VI. Inorganic Compounds.....	274
Gregory Paul Baxter: A Search for an Alkali Element of Higher Atomic Weight than Cesium.....	286
H. W. Foote: A Method of Determining the Hydrates Formed by a Salt.....	288
Jnanendranath Mukhopadhyaya: Electric Synthesis of Colloids.....	292
Louis J. Curtman and Alan G. Wikoff: The Detection of Bromides in the Presence of Thiocyanates, Cyanides and Ferrocyanides.....	298
M. A. Rosanoff and C. W. Bacon: On Fractional Distillation with Regulated Stillheads.....	301
Edward W. Washburn and Edward O. Heuse: The Measurement of Vapor Pressure Lowering by the Air Saturation Method.....	309
Note: Nitrochrome Gauze.....	321

Organic and Biological.

Richard Willstätter: Chlorophyll.....	323
Oscar F. Hedenburg: On the Esters, as Well as the Monomolecular β - and γ -Lactones, of <i>d</i> -Mannonic and <i>d</i> -Gluconic Acids; on Ortho-Bis- <i>d</i> -Galactonic Acid, <i>d</i> -Galactonic γ -Lactone and Its Mono-hydrate.....	345
Lambert Thorp and E. A. Wildman: Syntheses in the Diphenylmethane Series..	372
Treat B. Johnson and E. Heaton Hemingway: Researches on Pyrimidines. LXXIV. Synthesis of 4-Phenylecytosine.....	378
Treat B. Johnson and Joseph S. Bates: Researches on Hydantoins. XXX. Stereoisomeric Modifications of Benzalhydantoin.....	383
G. B. Frankforter and W. Kritchewsky: The Action of Chloral, Bromal and Benzaldehyde on the Polycyclic Hydrocarbons in the Presence of Aluminium Chloride.....	385
George A. Burrell and Frank M. Seibert: The Separation of the Constituents in a Natural Gas from which Gasoline is Condensed.....	392
E. Newton Harvey: Experiments on the Nature of the Photogenic Substance in the Firefly.....	396
F. Alex. McDermott: Experiments on the Nature of the Photogenic Processes in the Lampyridae.....	401
New Books: Qualitative Chemical Analysis; Food Products; Methods of Quantitative Organic Analysis.....	404

March.**General, Physical and Inorganic.**

Gregory Paul Baxter: Twenty-Second Annual Report of Committee on Atomic Weights. Determinations Published during 1914.....	407
Irving Langmuir: The Dissociation of Hydrogen into Atoms. Part II. Calculation of the Degree of Dissociation and the Heat of Formation.....	417
Gilbert N. Lewis and Merle Randall: The Free Energy of Some Carbon Compounds.....	458
Theodore W. Richards and Edward P. Bartlett: Compressibilities of Mercury, Copper, Lead, Molybdenum, Tantalum, Tungsten and Silver Bromide.....	470
Leason H. Adams: The Measurement of the Freezing-Point Depression of Dilute Solutions.....	481
T. W. B. Welsh: Anhydrous Hydrazine. II. Electrolysis of a Solution of Sodium Hydrazide in Anhydrous Hydrazine.....	497
A. Thiel: The Solubility of Certain Difficultly Soluble Silver Salts.....	508
Arthur E. Hill: The Relative Solubility of Certain Silver Salts.....	510
Marks Neidle: Absorption and the Surface Tensions of Aqueous Solution of Homologous Fatty Acids and Alcohols.....	513
Gregory Paul Baxter and Olus Jesse Stewart: A Revision of the Atomic Weight of Praseodymium. The Analysis of Praseodymium Chloride.....	516
Jas. Lewis Howe: Recent Work in Inorganic Chemistry.....	536
Note: A Surficial Burn Produced by an Unknown Radiation.....	549

Organic and Biological.

THE JOURNAL
OF THE
American Chemical Society

with which has been incorporated the

American Chemical Journal
(Founded by Ira Remsen)

THE DEVELOPMENT OF CHEMICAL RESEARCH IN AMERICA.¹

By IRA REMSEN.

Received November 9, 1914.

Our main object this evening is to do honor to the memory of Josiah Willard Gibbs. We owe to the generosity of Mr. William A. Converse the opportunity to come together for this purpose and for the further purpose of witnessing the award of the Willard Gibbs Medal. That I have been honored by the Chicago Section of the American Chemical Society in being selected as the recipient of the medal this year gives me much satisfaction and pleasure and I desire to thank you one and all for this marked evidence of your good will and good opinion. I should prefer to divert your attention from myself and my contributions to our science, and to devote my address to a presentation of the work of Willard Gibbs, who is the real guest of honor this evening, for he is surely present in spirit. I may as well confess, however, that I do not feel competent to discuss his work. I have, to be sure, studied it and gained some knowledge of it, but I have not mastered it, and have not, therefore, reached a stage in which it has become a part of my mental machinery. I do not think in terms of the phase rule. Probably I was born too early in the last century.

On the other hand, I knew Gibbs, though not intimately. In the early

¹ Abstract of an address before the Chicago Section of the Society on the occasion of the award of the Willard Gibbs Medal, May 15, 1914. The address was not written and the writer has had to rely largely upon his memory.

days of the Johns Hopkins University, in the academic year 1879-80, he gave a course on Theoretical Mechanics for the students of that university. As I was then a professor there, I necessarily met him frequently, and it has always been a source of gratification to me that I was permitted to know, even if not intimately, one whose work has shed so much luster upon the science of this country. I remember him very well, for even then, only shortly after the publication of his great memoir on the Equilibrium of Heterogenous Substances, those who were especially interested in scientific research in America looked up to him and hailed him as a leader, though many years were to pass before the world at large recognized in him one of the greatest and most original thinkers of his time.

I congratulate Mr. Converse upon his happy thought of calling a medal after this great man, and I congratulate you, members of the Chicago Section, upon the opportunity this act of Mr. Converse has given you of coming together to honor his memory.

In accepting the medal I have also accepted the obligation to address you upon some subject of interest to chemists and I have chosen as my subject "The Development of Chemical Research in America."¹ In the time at my disposal I shall not, of course, be able to do full justice to the subject, but I hope to be able to call your attention to the more important facts that mark the course of this development. I want, if possible, to point out the conditions under which research developed and became what it is today—epidemic. It was sporadic for many years, but it later became epidemic and is now, in fact, in a most acute stage.

There was not much research in this country in the eighteenth century. This is not surprising, for there were many other things to do. We were busily engaged in trying to make a nation and in developing our material resources. Nevertheless, during the last part of the eighteenth century there were a few who tried their hand at chemical research, and at the beginning of the nineteenth century a fair start was made.

In 1794 one of the great chemical workers of the time, Priestley, the immortal discoverer of oxygen, came to this country and settled at Northumberland on the Susquehanna River in Pennsylvania. He was in correspondence at that time with the authorities of the University of Pennsylvania, and he was also in correspondence with Jefferson into whose brain the germ of the University of Virginia had found its way. I mention Priestley because he was the first distinguished chemist in this country, but his work here did not have much effect on chemical research, for he devoted his attention almost wholly to theological questions.

¹ While I was engaged in collecting data for this address, Edgar F. Smith's "Chemistry in America" appeared, and I gladly acknowledge my indebtedness to this book.

The strongest scientific influence here at the time of which I am speaking was that of Franklin. He had produced a deep impression upon a group of people in Philadelphia, and this city became the chief center of scientific activity. For some time afterwards the leading chemists of America were those who came from that city. Among these the most prominent was Robert Hare. From all that I can gather from his writings he was really a very remarkable man. When he was but twenty years old he invented the compound blowpipe. That was a noteworthy achievement for a young man of twenty. It required a good deal of courage, ingenuity, and perseverance to devise such an apparatus. The compound blowpipe has been of great importance to science and industry. Some years ago I became interested in the double halides and published an article giving my views regarding the nature of these compounds. Soon after the appearance of my article I received a letter from Dr. Wolcott Gibbs telling me that Robert Hare had expressed similar views in 1821. He sent me his copy of Hare's Chemistry and I was astonished to read the chapter that had been written fifty or sixty years before my article. The line of thought was practically identical with mine, and it was expressed beautifully. Now, that man was active in Philadelphia from 1801 to 1847, during which time he was professor of chemistry in the University of Pennsylvania. He was both investigator and scientific philosopher.

Following Hare came Robert E. Rogers (1813-1884), James C. Booth (1810-1888), and T. Sterry Hunt (1826-1892). Hunt was an extensive experimenter and a prolific writer, and throughout his life exerted a marked influence upon chemical research in America. A contemporary of Hunt was John Lawrence Smith (1818-1883), who was also an enthusiastic investigator in the field of chemistry. In this connection should be mentioned the method he devised in 1853 for decomposing alkaline silicates by the use of calcium carbonate and chloride—now in general use. He left a considerable fortune, and some of it, as a trust fund, came to the National Academy of Sciences for the purpose of aiding and encouraging researches on meteorites.

We come now to two men who stood out very prominently as investigators. I remember when, in my youth, I became interested in chemistry I frequently heard their names, but what they investigated or why they investigated it I did not know. I refer to Wolcott Gibbs (1822-1908) and Frederick A. Genth (1820-1893). Gibbs was one of the highest-minded men I have ever known. He never wavered in his loyalty to science, and was true to his convictions to his last days. I visited him in Newport about two years before his death, when he was eighty-four years old. He took me out to his private laboratory—he had retired from active service at Harvard some years before that—and there he talked enthusiastically of work he had in mind for the future. It was an inspiration to

be with him. His influence on the development of chemical research in America cannot be overestimated.

Genth was of a different type. He was an able man, and a good, jolly German. He came to this country about 1848, and established a commercial laboratory. During the early years of his residence he and Gibbs, working together, carried out an elaborate investigation on the cobalt ammonia bases, in the course of which they brought to light a large number of complex compounds that proved to be of interest, and set many chemists to thinking. Now, I am almost inclined to say that the chief value of that work at that time was to be found in the fact that it impressed upon the minds of young American chemists the idea of the possibility of creative work in chemistry. What it was all about many of us did not know, but it fired our imagination and furnished us an ideal. I am sure that it had a marked influence for good upon many young men, and was a strong force among those that helped the development of chemical research among us. Genth afterward became professor of chemistry in the University of Pennsylvania in 1872 and continued active work to the end of his life.

Josiah Parsons Cooke (1827-1894), who was professor of chemistry at Harvard from 1850 to his death in 1894, was another of the six prominent chemical investigators whose influence was, and is, widely felt. He began research work early in his career and continued it to the end. It is interesting to note that he was entirely self-taught as a chemist. The work of his last years had largely to do with atomic weights.

Then there was Samuel W. Johnson, of Yale (1830-1909), whose influence was felt in the field of agricultural chemistry, and John W. Mallet (1832-1912), who worked at the University of Virginia and helped to keep the spirit of research alive. In this connection, we should also recall the name of M. Carey Lea (1823-1897), who, under great difficulties, held a true course. He had his own laboratory and had no students, so that his influence was perhaps not as great as it undoubtedly would have been if he had been in a position to found a school.

From what I have said it is evident that there was no time in the first half of the last century when chemical researches were not in progress in this country, but still the total result was small in comparison to the number of chemists. In 1872, when I began to study the conditions, I was surprised to find how few centers of activity there were in America and, on the whole, how little was being done. I had just returned from a residence of five years in Germany where I had devoted myself to the study of chemistry and had made a modest beginning in research. The life of the chemical investigator appealed to me very strongly as it has to many others. I was, in fact, fascinated by it, and my highest ambition was to secure a place where I could live that life. But there were few such places in America

at that time and they were filled. One of the first things that offered itself was a professorship of physics and chemistry in Williams College. That I accepted a place calling for a knowledge of physics shows that I had some courage. I am very glad I went there and had four years' experience in a college of that kind. I made lifelong friends and became familiar with an American college, and altogether the experience was one which I prize highly, but looking at it from the point of view of my scientific ambitions it was most discouraging. I did, however, secure a small room which I fitted up as a laboratory and, in solitude, I did a little work. There were times when it seemed as though I should give up, and settle down into a routine teacher. There was very little sympathy for my work. I remember that once just after the appearance of one of my first articles in the *American Journal of Science*, we had a faculty meeting in the college library. Someone picked up the number of the journal containing my article and some good-natured fun was poked at me when an attempt was made to read the title aloud. I felt that in the eyes of my colleagues I was rather a ridiculous object. But I was only about twenty-seven and perhaps a little oversensitive.

The Johns Hopkins University was opened in 1876 and early in that year I was offered the professorship of chemistry. It would be difficult, not to say impossible, for any one who has not had the same experience to form any conception of the hope and joy that came to us young men in the message from President Gilman that in the new university an effort would be made to provide for the needs of those who wished to carry on researches. Here was an opportunity of which many had been dreaming. It is needless to say that I accepted the offer with alacrity. President Gilman's injunction was simply this: "Do your best work in your own way." What could be finer? I bought all the apparatus I wanted and all the books I wanted. A simple laboratory was built. I had but three or four students and we went to work. Now, I am well aware of the fact that chemistry was not revolutionized as a result of our efforts, but we made a start in a new direction. Research became an essential part of the training of graduate students and soon they began to come in larger and larger numbers. There was great enthusiasm among these students. I have often been surprised and delighted to see how, generally, advanced students of chemistry (no doubt it is the same with other subjects) become deeply interested in the most abstruse problems the moment they begin to feel that what they are doing is going to be a contribution, even though a slight one, to the knowledge of the subject.

Soon another step was taken of necessity. After we had been working for about a year the question of publication presented itself. I had up to that time been sending my occasional articles to Professor James D. Dana for publication in the *American Journal of Science*, but now the

amount of material sent by me evidently frightened the editor, and in a short time my manuscript was returned with the statement that it would be necessary to find some other place to publish my articles, as they seemed too highly specialized and too voluminous for a journal of general science. Professor Dana very kindly suggested that I start a journal myself. After corresponding with the leading workers in chemistry with discouraging, as well as encouraging, results, I decided to act upon the suggestion, and early in 1879, thirty-five years ago, the first number of the *American Chemical Journal* was issued. For a number of years that journal contained the principal original contributions to chemistry that came from this country. It flourished far beyond my expectations, but within the last few years it became evident to me that the journal of our society was coming more and more to be looked upon by American chemists as the best medium of publication of their contributions and, somewhat reluctantly and with a sacrifice of sentiment, in January, 1914, I transferred my journal to the tender mercies of the society in full confidence that the interests of American chemists would, on the whole, be better served by consolidation than by separate existences. I think it probable that the *American Chemical Journal*, especially during the early years of its existence, exerted a stimulating influence upon chemical research in America, but no one can measure this influence, and it is perhaps idle to refer to it as a possible factor. Whatever the influences may have been that led to increased activity in chemical research in this country, it is certain that the increase was very marked soon after the time of which I have just been speaking. This was due, I think, largely to the fact that such excellent opportunities were given the little band of workers at Johns Hopkins. This led to similar opportunities being given to the workers in other institutions, and many of these profited greatly in consequence. It was not long before there were a number of centers of activity in America, and the number of those devoting themselves to research work has increased astonishingly. It is not necessary for me to speak in detail of the splendid work done at Harvard under the leadership of Hill and Jackson and Michael and Richards; of A. A. Noyes and his co-workers at the Massachusetts Institute of Technology; of Chittenden, and Wheeler, and Treat B. Johnson at Yale; of Bogert and Alexander Smith at Columbia; of Edgar F. Smith at the University of Pennsylvania; of Morse and Abel and Jones at Baltimore; of Bancroft and Orndorff at Cornell; of Gomberg at Michigan; of Nef and Stieglitz at Chicago; of W. A. Noyes at Illinois; of the group at Wisconsin; and those at California and Leland Stanford. The world is familiar with these names and the work they stand for. There are many other workers in the field. It would be a pleasure to me to mention them all. Now that I am to be counted among the old men of the day I may be permitted to express my great satisfaction

at the changes for the better that have taken place within my life time. Chemical research is in a healthy condition in our country and the signs of future growth are most promising. May I add in conclusion that, though circumstances have kept me out of the field of chemical work for some years past, I now see my way clear to entering that field again, and I can think of nothing that could give me greater pleasure than the prospect of taking up the work in chemistry that I had to abandon thirteen years ago. It is a little late for me to begin again, but I believe that I shall yet be able to experience some of the joys that came to me so abundantly in the past while struggling with my old, inanimate laboratory friends. The transformation from university president to chemist is complete, and I rejoice.

THE INCLUSION OF ELECTROLYTE BY THE DEPOSIT IN THE SILVER VOLTAMETER.

By T. W. RICHARDS AND F. O. ANDEREGG.

Received October 31, 1914.

I. Introduction.

The silver voltameter (or better, coulometer) is an instrument of such great importance in the exact measurement of the electrical quantity that its study by many investigators is highly desirable; therefore, the widespread attention which it has received during recent years is gratifying.

Since the classical researches of Lord Rayleigh and Mrs. Sidgwick¹ and F. and W. Kohlrausch,² carried out between 1880 and 1883, the subject has been studied in many places and from many points of view. The earlier of these investigations are mentioned in detail in the description of a protracted research carried out at Harvard University, and published years ago by one of the present authors in conjunction with two assistants.³ More recently the National Bureau of Standards, at Washington, the National Physical Laboratory, at Teddington, near London, England, and the Physikalisch-Technische Reichsanstalt, at Charlottenburg, Berlin, as well as other independent physical chemists, have conducted elaborate investigations concerning the nature of several irregularities in this instrument.

The most careful of these researches have verified the main calculations

¹ *Phil. Trans., (A)* **175**, 411 (1884).

brought forward in the earlier research conducted at Harvard; but unanimity has not yet been attained with regard to all the details.

Much time has been spent upon the question as to the purity of the electrolyte and the cleanliness of the apparatus, especially the porous cup recommended in the Harvard researches. These investigations were important perhaps from the standpoint of the average chemist, or especially that of the physicist unused to working with pure material, but there seems to be no important point (except perhaps the precise effect of acidification) in all this part of the recent work which was not appreciated at Harvard, fifteen years ago. Any one who has worked much upon atomic weights dealing with silver nitrate solutions would think of contaminating such a solution with organic material of any kind, especially filter paper; and there is no question that the silver nitrate used in the early Harvard work satisfied all the necessary requirements of the more recent critics. Moreover, it is obvious that a porous cup (if one is used) must be thoroughly washed free from either acid or alkali immediately before use. These patent facts might perhaps have been more emphasized instead of having been assumed almost as a matter of course, in the early Harvard papers; and if this had been done, time and trouble on the part of others might have been spared; the essential precautions were recognized long ago.

About the importance of pure materials, chemically clean apparatus, and electrically perfect insulation, there can thus be no doubt that all authorities are now agreed, the very recent work having emphasized the earlier conclusions; but concerning certain other irregularities of the silver voltameter, as has been said, there seems to be a real difference of opinion. Some of the investigators seem to think that organic impurity in the electrolyte is the *only* cause of excessive deposits on the cathode. That it is *one* of the causes there is no doubt; but it is equally clear to us that there are others. It is with regard to these points, especially, that the present work was undertaken.

The points in dispute concern in the first place the existence or non-existence of included mother liquor in the crystals deposited upon the cathode; secondly, the nature of the mother liquor (if any) thus included; thirdly, the existence or nonexistence of a surplus of silver in the liquid flowing from the anode; and fourthly, the efficacy of a porous cup as a means of promoting exact coulometric work through the separation of the anode and the cathode.

The present paper considers the first two of these points, *viz.*, those which concern the included mother liquor. It was necessary to settle these before any conclusive evidence concerning the other two could be obtained; for the decision depends largely upon small differences in weight of the precipitated silver crystals, and these differences might either be caused or be masked by differences in the amount of mother liquor included.

The experiments in the three national physical laboratories seem to have underrated the importance of this point, while exerting very praiseworthy care in other directions.

The first investigators to call attention to this very important source of error caused by inclusion of electrolyte were Lord Rayleigh and Mrs. Sidgwick. They determined the extent of the inclusion chiefly by heating the crystallized silver just short of redness. Their results showed that in many cases the inclusion of mother liquor unquestionably takes place; moreover, there could be no question that its amount varied according to circumstances. New solutions yielded less inclusion in the crystals than the old ones, and large crystals less than small ones.

These results were entirely verified by the Harvard work carried out many years afterwards.¹ The magnitude of the inclusion was found to vary from 0.003 to 0.03% from loss of weight on heating, and an average case was verified by analysis. The experience with silver crystals has been supported by plentiful experience with other kinds of crystals in the course of the Harvard work upon the atomic weights. Indeed, it is not too much to say that we have never been able to obtain crystals of any kind free from traces of mother liquor, although, of course, the amount included varies greatly according to the details of crystallization.²

In spite of this experience, Gray³ and van Dijk⁴ denied the existence of such included mother liquor, and Smith, Mather and Lowry have supported these doubters,⁵ as well as Jaeger and von Steinwehr.⁶ A study of these papers, however, shows that either the accuracy of the work was not adequate, or else the heating was not carried far enough to prove the point. Unquestionably, van Dijk and Smith, Mather and Lowry in most cases failed to use a temperature sufficiently high to drive off the inclusions and probably this was the case also with Jaeger and von Steinwehr. Attention has already been called to the need of heating the silver to so high a point that the metal has become somewhat softened.⁷ The mother liquor is then set free by a series of small explosions or decrepitations, and the temperature needed is over 550°. It is quite possible, indeed, that the last traces of included matter are not expelled until the silver is completely fused,⁸ but very nearly all of it is driven out at dull redness,

as we have repeatedly shown. In discussing their experiments on this point, Jaeger and von Steinwehr make a somewhat incomprehensible correction for loss of weight of the crucible during heating. A clean platinum crucible, in our experience, heated to a temperature below redness, does not usually lose an important amount in weight, although they applied such a correction. If this doubtful correction were omitted, their results tend to confirm ours.

The recent work carried out by the Bureau of Standards seems not to have heeded sufficiently the inclusion of mother liquor, in spite of the arguments previously presented concerning it. More recently results which have been obtained by Hulett in careful collaboration with Duschak and with Laird¹ have entirely confirmed the conclusions of Lord Rayleigh, which had indeed been thoroughly verified at Harvard long before the Princeton work was begun. Hulett and his collaborators adopted van Dijk's somewhat questionable preliminary operation of scraping the crystals from the platinum dish. This is necessary, if the crystals are to be heated in a tube, but it has one important disadvantage, namely, that this forcible treatment of the crystals might very well open cells containing mother liquor which would otherwise remain closed, especially cells between the crystals and the platinum cathode. In his later work with Laird, Hulett used melted tin as a solvent for the silver; but one cannot help thinking, especially because of the large amount of carbon dioxide which he found, that dust had, during some stage of the operation, found its way into the tube. Neither of these methods (although each gives interesting results) seems to provide exactly the information desired, namely, the weight of the inclusions actually held by the deposit as weighed.

The attempt to determine the inclusions by attacking the silver deposit with mercury, as practised by the Bureau of Standards,² is likewise of uncertain value, because the solubility of silver in mercury is very slight (as we have found by careful experiment³) and the metal is merely converted into a solid amalgam which might withhold some of the included impurities.

For these reasons it is not necessary to discuss more fully here the interesting details of all this recent work. The very careful researches of Hulett and his collaborators substantiate that previously carried out at Harvard in showing, first, that the inclusions are often important in amount, and secondly, that they vary considerably according to the details of experimentation. Thus, for an accurate determination of the weight of

¹ Hulett and collaborators, *Trans. Am. Electrochem. Soc.*, **12**, 257 (1907); **22**, 345 (1912).

metallic silver deposited by the current the amount of inclusion must be determined in each experiment.

Nevertheless, it seemed desirable to institute new experiments touching the more essential points involved. In the course of these experiments, the weight of silver chloride obtained from the coulometric deposits was compared with the weight of silver chloride obtained from perfectly pure silver. This gives theoretically the most conclusive method of determining the amount of the impurity, but is, of course, difficult of execution. Again, crystals were ignited at high temperatures and care was taken to find the point at which constancy of weight was attained, and also the point at which appreciable volatilization of the silver began to invalidate the result. Yet further, a number of deposits were scraped from their cathodes à la van Dijk and Hulett. Both crystals and cathode were washed with pure water before ignition, and it was thus found that cells containing silver nitrate solution had really been opened up by the scraping. The analyses of these crystals pointed to the same conclusion. Finally, methods for determining the amounts of inclusion having been settled, comparisons were made of the extent of inclusion involved in the various forms of the coulometer. These experiments are set forth in detail below. One does not see how any candid or unprejudiced reader, however he may have felt with regard to previous contributions on this subject, can escape the inference that inclusions in silver crystals are really important and that no coulometric work is complete until the amount which pertains to the particular method employed is discovered by actual analysis.

II. Details Concerning the Apparatus.

The porous cup coulometer as used consistently throughout this research as a standard instrument was precisely similar to that recommended by one of us in connection with G. W. Heimrod, twelve years ago.¹

A large platinum crucible with a lip, weighing about 60 g. and containing about 120 cc. was used to contain the catholyte. In it was suspended from a glass arm a small porous cylindrical Pukal cup which contained the anolyte, always kept at least 1 cm. in level below the catholyte. Everything was thoroughly insulated by glass and paraffin, and the whole was arranged under a bell-jar to protect from dust or outside impurity. The inner level was maintained constant either by a constant level siphon or by a pipet. The anodes consisted of metal carefully prepared in a pure state according to the usual method,² fused in hydrogen on lime in the electric furnace. They were scraped with pure sea-sand and etched with pure dilute nitric acid. In a few cases they were plated with additional silver electrolytically. The porous cups were, of course,

¹ *Proc. Am. Acad.*, 37, 415 (1902); *Z. physik. Chem.*, 41, 302 (1902).

² See Richards and Wells, *THIS JOURNAL*, 27, 481 (1905).

thoroughly digested with nitric acid and then boiled with repeated portions of the purest water until every trace of acid had been washed from their pores. In the crucial portion of the work this was done after every experiment.

The nitric acid used throughout the work was always the middle third, carefully redistilled, of an acid already very pure.

The silver nitrate used as electrolyte was prepared either from silver made according to the method of Stas, or in the later experiments from silver precipitated by acidified ammonium formate. The salt was always crystallized twice, the first time from a slight excess of nitric acid and the second time from pure water, a trace of acid remaining in the mother liquor from the previous crystals. This method provides, as the work of the Bureau of Standards has shown, a solution which is free from basic salt. In some cases also solutions which had already been used in the coulometer were filtered through asbestos and then recrystallized three times, the first two times from 10% acid and the final time as before without adding any acid. Each batch of crystals was centrifuged as usual. All the water used in the important parts of this research was purified by redistilling first from alkaline permanganate solution, and again from a trace of sulfuric acid.

For convenience in regulating the current, an ampere meter was included in the circuit. Unless otherwise stated a current of about 0.25 ampere was used in the work. After the electrolysis was completed, the porous cup was removed and the catholyte was siphoned into a small labelled crystallizing dish, leaving a few cubic centimeters of the solution in the bottom of the large crucible. The occasional loose crystals of silver which either remain at the bottom or float on the surface of the electrolyte are thus kept in the original vessel. The cathode vessel was then filled with pure water, which was immediately siphoned into a large labelled dish; and this process of washing was repeated several times at even greater intervals until evening, when the crucible filled with the purest water was allowed to stand over night. On the next morning this wash-water was tested in the nephelometer with sodium chloride against pure water, to see if all the accessible silver nitrate had been washed from the pores of the crystals. In all cases, except two, this wash-water was found to be free from silver nitrate, and in these two cases another change of water left till noon showed no traces of this salt. Finally the deposit was rinsed with very pure water, a few milliliters of which were left in the crucible. Any minute crystals of silver that may have passed over were recovered with a small platinum spatula. Our experience agrees with Hulett's, that a particle smaller than 0.01 mg. may be seen and recovered. The crucibles were heated two hours at 160°, after the water had been evap-

orated, in electric ovens, cooled and weighed as before with all the precautions for exact weighings.

A building with its temperature regulated by thermostats, a balance very free from vibration, and favorable conditions of every kind, were of great assistance in making accurate weighings of the cathode. The weighings were regularly duplicated to within 0.02 mg.

III. Inclusions Determined by Analysis.¹

After a regular double electrolysis (with two coulometers in series) had been made, the crucibles containing the weighed deposits were placed in large covered beakers nearly filled with warm water, and a slight excess of redistilled nitric acid was added. When the silver had been completely dissolved, the solution was quantitatively transferred to a two-liter precipitating flask. To the large bulk of solution an excess of very pure hydrochloric acid was gradually added—enough to precipitate all the silver—leaving dissolved an excess of ionized chlorine, in hundredth normal concentration.²

The precipitate was agitated till it had thoroughly coagulated, and allowed to stand in a dark room for twenty-four hours with occasional shaking; the filtering was done through a tared Gooch-Monroe crucible. The precipitate was washed ten times with wash water containing hundredth normal hydrochloric acid, being transferred to the crucible with the same wash water, and finally dried for five hours at 180–190°, cooled and weighed. The bulk of precipitate was then placed in a previously ignited porcelain crucible; and after weighing, the silver chloride was fused in a porcelain air bath. The fused mass was nearly colorless in all cases. Except silver chloride, the only substances present in this analysis are volatile, hence the process is an unusually precise one. A trace of silver chloride remaining in the precipitating flask was dissolved in a little ammonia, determined in the nephelometer, and added to the main weight.

The vacuum corrections for metal and halide are respectively, -0.031 mg. and $+0.071$ mg. per g. These were duly applied, and the calculation was carried out on the assumption that the atomic weights of the two elements are respectively, 107.880 and 35.459. The results are given in

¹ This method was tried once before at Harvard, the analyses having been made by Mr. E. Collins near the beginning of his part in the research (*Proc. Am. Acad.*, 35, 139 (1899)). No claim was then made for great accuracy, but the outcome was in favor of a slight inclusion. The cause of the errors in Expts. 35 and 36 noted by Rosa (*Bur. Standards, Bull.* 10, 518 (1914)) cannot now be traced, as the original notes are no longer accessible. In any case, the older analyses do not compare in authority with those given below.

² Forbes (*THIS JOURNAL*, 33, 1937–1911) has shown that silver chloride is least soluble in such a concentration of chloride ions. Calculating from the solubility product (2×10^{-10}) it would take five liters of solution to dissolve 0.01 mg. of silver chloride, and hence no correction need be applied.

Table I; the table is easily comprehensible. For each of the last two analyses the products of the two coulometers were united for analysis. The calculated figures in the last column make allowance for the fact that the included mother liquor must have contained about 8 or 10% of silver nitrate, the silver in which must have been precipitated as chloride and weighed with that coming from the electrolytic metal.

Evidently the actual weight of silver chloride found was always less than the theoretical weight. Hence the silver contained included impurity.

The quantity of inclusion thus found by direct analysis (0.014%) is close to that found by Richards and Heimrod, 0.018.² The present series of analyses determines this quantity by a method quite different from the old way.

In order to forestall the criticism that the deficiency thus found might simply be due to loss of silver during the analysis, very pure fused silver was prepared and analyzed with exactly the same precautions.

TABLE II.—ANALYSIS OF PURE FUSED SILVER.

Corrected wt. Ag. Grams.	Corrected wt. AgCl found. Grams.	Calculated wt. AgCl. Grams.	Diff. Mg.	Diff. in %.
6.22211	8.26738	8.26725	+0.13	+0.002
5.16568	6.86361	6.86359	+0.02	+0.000
5.18476	6.88876	6.88893	-0.17	-0.002
16.57255	22.01975	22.01977	-0.02	0.000

This result is very different from that previously found in the case of the crystallized electrolytic silver, and corresponds exactly with the value 35.459 for chlorine. The international value 35.460, also, is within the limit of experimental error. The evidence is very strong, therefore, that the analytical procedure was correct, and hence that the electrolytic silver prepared as we had prepared it, contains more than one part in ten thousand of included mother liquor.

¹ If Cl = 35.460, this value would be 0.0148%.

² *Loc. cit.*, p. 435.

III. Inclusions Determined by Heating the Deposits in the Cathode Crucible.

The ignition of the deposit for the purpose of determining the inclusions by loss of weight has been often used in the past, first by Lord Rayleigh and Mrs. Sidgwick, and later by many others. Some, trying to use it, have failed to heat the silver hot enough, as already stated.

In our experiments, after the crucible with its deposit had been washed, dried and weighed as usual, it was placed on a quartz triangle in a dark room. A clean porcelain crucible was inserted into the mouth to protect the material from dust and to cool and catch traces of silver vapor. The platinum was heated very carefully, with a burner held in the hand, until it attained dull redness, just barely perceptible in the dark. Great care was used to not exceed this temperature, and to heat the crucibles all over, as evenly as possible. The crucible was then cooled, and weighed once more.

Such heating slightly alloys the two metals; on dissolving the silver in nitric acid a perceptible amount of platinum remained. In preparation for a new trial, the inner surface was afterwards scrubbed, washing finally with acid and water. The crucibles lost a few tenths of a milligram each time, due to the removal of the platinum. Burnished crucibles suffered much less than those roughened by continuous use. This complication, of course, had not the slightest effect upon the quantitative experiment.

To settle the question raised by Jaeger and von Steinwehr, as to whether a platinum crucible alone loses weight when heated, one of ours was heated five times, just as if it had contained silver. The total loss was only 0.05 mg., or 0.01 mg. for each heating. This is negligible, but the corresponding correction was applied to each result for the sake of completeness.

The results concerning the amounts of included electrolyte found by heating the precipitated silver are summarized in Table III. Each figure is calculated from the actual loss on heating by adding to that quantity 6% of its value, to allow for the silver which must have remained from the included nitrate decomposed by heat. This will be explained more fully later. The first column records the amount of inclusion in silver precipitated on a crucible which had been somewhat scratched and roughened by van Dijk's process of mechanical removal of previous precipitates; the second column records the result for freshly burnished crucibles (both used as porous-cup coulometers); the third column gives the amount in an instrument according to Kohlrausch (the first four results coming from burnished crucibles and the last three from rough ones)³, the fourth column shows the increased inclusion when some of the anolyte is permitted to come into contact with the cathode deposit, and the last column shows the greatly increased effect when a large surface receives the silver crystals. The deposit varied in weight from 1.9 to 3.1 g. In order to be sure that no

silver volatilized during the ignition, the porcelain crucible which had been used as a cover during all the heatings was warmed with nitric acid; but no silver was found in this liquid on testing in the nephelometer.

TABLE III.—INCLUSIONS IN PRECIPITATED SILVER, FOUND BY HEATING.

(Expressed in fractions of per cent of weight of silver.)

Porous cup roughened crucible.	Porous cup burnished crucible.	Kohlrausch form.	Cathode less protected from anode.	Porous cup, large cathode vessel (roughened).

0.0174	0.0097	0.0039
0.0194	0.0100	0.0115
0.0171	0.0100	0.0045
0.0174	0.0119	0.0055
0.0178	0.0115
0.0125
0.0107
0.0139
Av., 0.0155	0.0100	0.0083	0.0221	0.0332

These results are worthy of careful study.

In the first place, one notes that the average of the first column, including all the results obtained with the ordinary somewhat roughened porous cup voltameter, is 0.015—a figure close to that found by the actual analysis of the silver, 0.014, recorded in the last section, as well as to the earlier results found at Harvard and the still earlier work of Lord Rayleigh.

In the next place, it is clear that a roughened crucible considerably increases the inclusion, its figure being 0.015 instead of 0.010 found in the case of a burnished crucible.

Again, it is apparent from Column 5 that other things being equal, the inclusion is approximately proportional to the surface on which the silver is deposited—for the large platinum beaker-crucible used in this series had about twice the surface of the smaller vessel used for the experiments in Column 1, and the inclusion was about double. This surface effect is doubtless the real cause of the so-called "volume effect" noticed by various other experimenters,¹ for they failed to observe and correct for this greater occlusion which occurs on a larger surface. These figures give striking evidence of the importance of determining the amount of inclusion in each case, and by their final consistency strongly support the other work.

The surface-effect, producing greater inclusion, is doubtless also the reason why the Kohlrausch form of voltameter gave a lesser deposit; for in this form the receptacle placed under the anode to receive the "anode slime" cuts off nearly half of the cathode from usefulness, and the silver is actually deposited upon only a part of the platinum surface which would

¹ See for example Rosa, *Bull. Bur. Standards*, 9, 514 (1913).

be available in the porous-cup voltameter. This, of course, by increasing the current density, diminishes the practical maximum current strength which the instrument can safely endure, and makes a large crucible no more efficient than a small one would be with the porous cup.

Finally, it is evident from Column 4 that the anode impurities promote the inclusion, in confirmation of the Harvard work of 1900-1902 and of Hulett's later results.

Because, also, as the work at the Bureau of Standards has shown, by very extended experiments, both current density and temperature affect the size and distribution of the crystals, these factors also must affect the inclusion.

Evidently it is impossible to apply a correction so variable to any work upon this subject, either one's own or that of others, without an intimate knowledge of every detail. The only satisfactory method is to *determine with due precaution the amount of included electrolyte in every crystalline precipitate*; and no work in which this has not been done can possess final authority, at least as regards the exact weight of the precipitate.

IV. The Nature and Distribution of the Inclusion.

It is, of course, possible that the mother liquor included in the crystals is not of exactly the same composition as the original electrolyte. Around the cathode during active electrolysis the solution of silver nitrate is necessarily diluted; and the solution may be caught and imprisoned in this diluted condition.

A moment's thought will show, however, that the exact concentration of the imprisoned mother liquor is not a serious question. For example, if the total inclusion is 0.015%, a knowledge of the composition of the mother liquor within 7% would correspond to an accuracy of 1 part in 100,000 of the crystallized silver. This is a high degree of accuracy, which rarely needs to be exceeded. Supposing, therefore, that one starts with a 10% solution of silver nitrate, more than half of the dissolved substance might be eliminated without causing a serious effect upon the result. The error from any possible change of concentration is, therefore, less than the possible error which might be caused by scraping the crystals from the dish; for this process (as will be shown) allows water to evaporate from cells opened by abrasion. *The really important point, as usual, is to determine the amount of included water.*

On this account we have made no search as to the exact composition of the included mother liquor. The analyses made by Hulett seem to be more than sufficient for the purpose. Although variable, they indicate that the enclosed liquid under the conditions involved does not lose anything like as much as half of its dissolved salt.

As already stated, the presence of carbon dioxide, found by Hulett

in the gases obtained from the silver, is probably to be ascribed to dust, which doubtless furthers occlusion of mother liquor. No other reasonable source is assignable. At a high temperature this dust, even if protected from air, would burn in the oxygen of the nitric acid and be expelled. Obviously, therefore, the carbon would be eliminated from the final result, whether its weight were calculated from the amount found as a gas, or simply from the loss of weight of the heated silver. It is almost impossible to exclude such minute traces of dust under ordinary conditions; therefore, it is comforting to feel that in this case, at least, their influence is negligible.

One milligram of the original 10% electrolyte leaves 0.063 mg. of silver on ignition; and 8% solution would leave 0.051 mg. The cathode occlusions are probably between these limits, which are close enough for the purpose. Hence, to obtain the exact weight of the silver deposited electrolytically as metal, one must subtract from the weight of the precipitate ignited at a dull red heat about 6% of the loss on heating, as has been done above. As already stated, this is quite accurate enough. Incidentally, it may be stated, that a similar correction was thus applied in the early Harvard investigations.¹ For most purposes, where the weighings are not carried beyond 0.1 mg. the correction may be neglected altogether; the weight of the silver crystals heated to incipient redness may be taken directly as the weight of the metallic silver precipitated by the electrolysis.

The question concerning the distribution of the inclusion in the deposit is of more importance. Is the imprisoned liquid wholly in the body of the crystals, or is part of it held between the crystals and the platinum cathode? If the latter is the case, van Dijk's and Hulett's method of removing the crystals from the dish may open a part of the cells, allowing some of the liquid to evaporate; thus both the weight and concentration of the included solution may be wrongly estimated. This is a matter easily susceptible of experimental decision; and our study of it is recounted below.

In the first place, a number of deposits were prepared with the purest electrolyte and all the precautions already described. After most carefully washing, weighing and drying the deposit, each deposit was removed as far as possible from the platinum cathode with a platinum spatula. Both dish and spatula suffered somewhat, and the detached crystals of silver contained some platinum; but this did not affect the main point in question. The crystals were placed in a test tube and washed with a little water, which was then filtered through a Gooch crucible provided with quantitative asbestos. The cathode crucible was similarly washed, and its wash water similarly filtered. These wash waters were tested in the nephelometer by comparison with standard silver nitrate solution with every precaution.

¹ *Proc. Am. Acad.*, 37, 421 (1902); *Z. physik. Chem.*, 41, 308 (1902).

Table IV summarizes the results obtained with crystals deposited on cathodes somewhat roughened by this drastic treatment.

TABLE IV.—SILVER NITRATE CONTAINED IN THE WASH WATER FROM THE CRUCIBLES AND CRYSTALS.

	3.19439	0.026	0.012	0.038	0.0012
Total, 22.64761		0.169	0.182	0.351	0.00155

Thus, on the average, every gram of silver precipitated in this way enclosed 0.015 mg. of silver nitrate between the crystals and the dish. It remained to discover the amount of mother liquor imprisoned within the crystals themselves.

After drying these washed crystals for at least an hour at 160°, they were placed in a quartz crucible provided with a cover of the same material. When carefully weighed, they were heated in the flame of a Bunsen burner to dull redness. This heating was usually accompanied by a crackling sound, as the inclosed substances made their escape. The cooled crucible was weighed, and again heated, cooled and weighed as before until constant weight had been obtained.

The values obtained by this method gave a measure of the volatile matter in the crystals, which must be corrected for residual silver as before. In four determinations, 7.22 g. of silver lost 1.23 mg., or 0.017%. Corrected for residual silver from the enclosed nitrate, this becomes 0.018%.

Because of a fear lest some silver might have been lost by volatilization from the quartz crucible, the test was repeated, with a quartz test tube, fifteen centimeters long, in place of the crucible. In this test tube there were heated two portions of crystals which had been accumulated from several electrolyses, scraped from the crucibles and afterwards washed as before. To insure precision in weighing, a tare was used, consisting of a similar amount of silver which had already been heated in the crucible. A small tube of radioactive substance was kept in the balance case to remove any electrostatic charges from the tubes, and every precaution was taken to insure accuracy. During the ignition a thin-walled, cone-shaped glass tube was inserted well down into the top of the quartz tube, which was then inclined at an angle of 30–45° with the horizontal, and heated in a Bunsen flame. From this arrangement no trace of silver vapor could escape during the ignition. The inner glass

tube was duly tested for volatilized silver by treatment with nitric acid. In one case a trace was found, and due correction applied. In the second trial none was found.

When the silver had reached constant weight on successive treatings, the tube was evacuated with a water pump and again heated to see what effect the absence of most of the oxygen would have. Von Wartenburg¹ suggests the formation of silver oxide at high temperatures to explain the fact that silver is more volatile in oxygen than in an atmosphere of nitrogen or in a vacuum. The heating in the partial vacuum produced no perceptible effect on the weight. Two trials were made, using 10.1 and 9.8 g. of crystallized silver, respectively. The corrected losses of weight were 1.37 mg. and 1.12 mg. (or 0.0135 and 0.0115%), respectively. Averaging the results, we see that these specimens of washed silver contained 0.0125% of mother liquor. To this must be added the amount of silver nitrate which had been washed from their abraded surfaces, namely 0.00155 (see Table IV), making 0.014% in all. This is somewhat less than the loss of weight found in similar deposits when the crystals have not been removed from the dish (see Table III); hence it would appear that the removal of the crystals opens some cells which otherwise would remain closed at 160°, and allows the water to evaporate from the previously imprisoned silver nitrate. Hence it is clear that the method of van Dijk and Hulett is probably not an adequate way of determining the actual total amount of included mother liquor which is weighed with the crystals while the latter are still adhering to the dish.

Another very strong piece of evidence in support of these conclusions about the included mother liquor is to be found in the comparison of the final weights, after ignition, of deposits upon large and small coulometers in the same circuit. Whereas before heating the two gave very different results, after heating they were almost identical.

TABLE V.—WEIGHT OF DEPOSITS IN LARGE AND SMALL POROUS-CUP COULOMETERS.

1st Expt.	Weight after drying at 160°.	Weight after ignition at dull redness.	Final weight after cor. for residual Ag from AgNO ₃ .	Weight of included electrolyte.
Large coulometer.....	1.89559	1.89494	1.89490	0.00069
Small coulometer.....	1.89525	1.89492	1.89490	0.00035
Difference.....	0.00034	0.00002	0.00000	0.00034
2nd Expt.				
Large coulometer.....	3.13902	3.13812	3.13807	0.00095
Small coulometer.....	3.13868	3.13808	3.13805	0.00063
Difference.....	0.00034	0.00004	0.00002	0.00032

The second and third columns of figures show how nearly alike the results are after the ignition: that is to say, the apparently large difference

¹ *Z. Elektrochem.*, 19, 482 (1913).

between the results of the two sizes of coulometers (which would have been left unexplained as a "volume effect" if the methods of the three national bureaus had been used) is annihilated by the simple device of heating the crystals to a temperature high enough to drive off the included water.

In a recent able article by Bates and Vinal¹ appears the following statement: "The whole question of inclusions has been critically discussed by Rosa, Vinal and McDaniel.² Their opinion is that the deposits so perfectly crystalline as those formed from the purest silver nitrate do not contain significant inclusions." To us it seems that any such superficial evidence is far from convincing. One of us has shown repeatedly³ that no matter how beautiful a crystal, or how perfectly crystalline and transparent its structure may be, yet when it is crystallized from aqueous solution it is almost, if not quite, certain to contain some of the mother liquor, either in accidental submicroscopic cells or in "solid solution." Indeed, a careful review of this latest published comment, in the light of the foregoing experiments, fails to reveal any adequate argument against our conclusion.

V. The Purity of the Ignited Deposit.

Only one final question remained: is crystallized silver, which has been thus heated at a dull red heat, really pure silver? Upon this point the validity of the whole coulometric process depends. From the fact that the amount of inclusion as found by analysis agreed closely with that found by heating the silver, it is clear that the heated crystals must have been very nearly pure; but the matter was clinched by actual analyses of two of the specimens remaining from the work described on p. 20. On solution in nitric acid, each preparation was filtered through a Gooch-Munroe crucible with every quantitative precaution, and the residual platinum derived from the cathode was carefully weighed. The analysis of the solution was conducted by precipitation with pure hydrochloric acid exactly as on page 13.

¹ THIS JOURNAL, 36, 932 (1914).

² Bur. Standards, *Bull.* 10, 516 (1914). The main quantitative evidence depended upon a single experiment (p. 522), in the interpretation of which the erroneous assumption was tacitly made that inclusion does not exist in the porous cup voltameter, and is the only error in the filter-paper voltameter. The fallacy will be explained more clearly in the next paper upon this topic, to appear shortly.

³ *Proc. Am. Phil. Soc.*, 42, 28 (1903); THIS JOURNAL, 33, 885 (1911).

The conclusion is, therefore, that such finely crystallized electrolyzed silver, which has been ignited at a dull red heat, contains less than 0.001% of impurity. Except for the difficulty of removing the silver from the cathode, and from the clinging contamination of platinum therefrom, this would be a good method of making very pure metal. Possibly the fine crystals precipitated in an electrolytic silver-tree, or by formate, would, on gentle ignition, show equal purity; if so, either of these very obvious processes would be extremely convenient for the preparation of this substance for many quantitative purposes.

In a recent paper Bates and Vinal¹ have compared in a very interesting way the iodine coulometer of Washburn with the silver coulometer. Deviations among the results were noticed, but no satisfactory explanation of them was given. When, however, it is remembered that the investigations made no allowance whatever for included mother liquor, and when one studies the tables on the foregoing pages in this paper, the reasons for the deviations become manifest. With the porous cup voltameter the inclusion is greatest on the largest surface; hence such deposits were the heaviest, as they found. The Kohlrausch form,² because it restricted the surface of the large vessel, would be expected to yield a result between the two; moreover, the error due to anolyte, to be discussed in a subsequent paper, may enter into its results, as well as into those from very diminutive coulometers. The exact correction of these results for inclusions is unfortunately impossible, because the inclusion varies with the extent and roughness of the surface of the cathode. But an approximation may be made if we assume the 120 cc. porous-cup voltameter (which gives the lowest results) as a standard, and then correct its indications by applying the average correction which we have found in this present work (0.015%). This would, of course, raise the calculated atomic weight of iodine by this percentage, if silver is assumed as the standard. Taking silver as 107.88, iodine was found to be 126.898 by Vinal and Bates with the small porous-cup instrument; but corrected for inclusions in the silver this becomes 126.917. This corrected value is in much better agreement with Baxter's best result, 126.932, than before. The remainder of the difference may perhaps be ascribed either to the need of a larger correction for inclusions, or possibly to the existence of a trace of chloride of iodine in the iodine used by Bates and Vinal for standardization. The latter's result is almost identical with Baxter's preliminary value, 126.916.³

The assumed international value of the Faraday is also, of course, affected to an equal extent by inclusion. If, as we cannot but believe,

¹ THIS JOURNAL, 36, 916 (1914).

² Smith's large new form is a modification of the Kohlrausch arrangement.

³ Bates and Vinal took great pains in the purification, but not so much as Baxter. See Baxter, THIS JOURNAL, 32, 1591 (1910); also *Proc. Am. Acad.*, 40, 419 (1904).

the 1.11800 mg. of silver supposed to be deposited by a coulomb contained inclusions, the true value may well be nearer 1.1179. It is profoundly to be regretted that all the able recent experimenters on this absolute value seem to have entirely overlooked the importance of this matter.

We are much indebted to the Carnegie Institution of Washington for apparatus used in this research.

Summary.

In confirmation of earlier work by Lord Rayleigh and that at Harvard, as well as of the subsequent work of Hulett, the presence of included electrolyte in the crystallized silver deposited in a silver coulometer (voltameter) has been shown in the following ways:

First, by quantitative analysis of the crystals after drying to constant weight at 160°.

Secondly, by ignition of the crystals on the cathode at a dull red heat.

Thirdly, by ignition of the crystals, separated from the cathode, in a quartz test tube, arranged so as to prevent evaporation of silver.

Fourthly, by showing that simultaneous deposits which were unequal in weight before ignition had attained equality after ignition.

The included mother liquor was shown by quantitative experiments to be partly within the crystals, and partly between the crystals and the walls of the cathode.

The quantity of the inclusion varies, increasing (as would be expected from the immediately foregoing statement) with increasing surface and with increasing roughness of the cathode. It may vary from 0.004 to 0.035% of the weight of the silver. The silver remaining after the ignition was shown to possess a very high degree of purity, and at incipient redness it was shown to be essentially nonvolatile during brief treatment.

The experiments of the three national bureaus of America, England and Germany, while illuminating in many respects, failed to throw light on the matter, because of incomplete experimentation. Either the temperature of ignition was inadequate, or some other oversight intervened—as, for example, in the attempt to dissolve the precipitated metal in 50 times its weight of mercury when 2500 times its weight are really needed for complete solution.

Because of the variation of the amount of inclusion according to circumstances, it is unfortunately impossible to correct older results. But there seems to be no question that correction is necessary, especially in the case of the large dishes used by Smith, Mather and Lowry. Hence, much of the work should be repeated. The correction affects the value of the electrochemical equivalent, the Faraday, the value assigned to the Standard Weston cell, and all ratios of atomic weights determined electrically; hence, it is a question of importance.

THE INTERACTION OF HYDROGEN AND CHLORINE UNDER THE INFLUENCE OF ALPHA PARTICLES.

By HUGH STOTT TAYLOR.

Received October 26, 1914.

Recent researches upon the photochemical combination of hydrogen and chlorine have advanced considerably our knowledge of and insight into the reaction itself and to a certain extent the general theory of photochemical reaction. The work of Chapman and his co-workers has, to a great degree, elucidated the abnormalities previously observed and due, in many cases, to the presence of impurities. In the later investigations of the series,¹ by variations from equimolecular mixtures of the two gases, the study of the kinetics of the reaction was commenced. Towards the solution of the latter problem the researches of Bodenstein and Dux² have materially contributed. By the employment of a very ingenious method of measurement, eliminating the necessity of employing water as absorbent for the hydrochloric acid formed, the following points were established:

1. The combination of hydrogen and chlorine in light is a reaction of the second order, the velocity being proportional to the square of the chlorine concentration. Hydrogen is without influence so long as it is present to the extent of at least $\frac{1}{4}$ of the amount of chlorine. At smaller hydrogen concentrations the velocity decreases slightly.

2. The hydrochloric acid formed is without influence on the velocity.

3. Water vapor within certain limits (0.004–2.3 mm.) is also without influence.

4. Oxygen retards the reaction, such that the velocity at all stages of the decomposition is inversely proportional to the oxygen concentration.

For the interpretation of the equation of reaction thus obtained:

$$+ \frac{d(2\text{HCl})}{dt} = k \frac{J_0 [\text{Cl}_2]^2}{[\text{O}_2]}$$

Bodenstein³ has developed a theory of photochemical reaction velocities and applied it to practically all the measurements in this branch to be found in the literature. According to this theory the initial absorption process in any photochemical change is to be regarded as a photoelectric effect, as a rupture of the molecule at the expense of the absorbed light energy into a positive radical—an atom or with more complex substances a molecule with a free valence—and a free electron. Both portions may lead to chemical reaction, the positive radicals in that they are, chem-

¹ Chapman and Underhill, *J. Chem. Soc.*, 103, 496 (1913).

² *Z. physik. Chem.*, 85, 297 (1913).

³ *Ibid.*, 85, 330 (1913).

ically, exceedingly active, the electrons in that they may attach themselves to molecules and so activate them as to take part in chemical change. A distinction is drawn between primary light reactions, in which the positive radicals enter into combination, and secondary reactions in which the molecules activated by the electrons take part in the reaction, the electrons, after reaction has occurred, being again free to attach themselves to and activate other molecules.

A further development of the theory, as regards the relation of light energy absorbed to chemical reaction produced, reveals a marked point of difference in regard to the two classes of reaction. In the primary reactions, for every molecule brought into combination a quantum of absorbed energy or a small number of quanta is regarded as necessary. In the secondary reactions, owing to the function of the free electron as catalyst, an energy quantum should be in a position to bring about the combination of a large number of the reacting molecules.

If it be true that the first stage of a photochemical reaction, as assumed in the theory of Bodenstein, consists of a photoelectric effect, the rupture of a molecule into a positive radical and an electron, then the theory and the method of development should find rigid application in all such chemical reactions as are effected under the influence of other forms of energy, provided that under such influence the rupture of the molecule with the formation of free electrons may be postulated. It is obvious, therefore, that such processes as are effected by means of electrical energy in gases (*e. g.*, under the influence of the silent electric discharge or of Röntgen rays) or, on the other hand, processes determined by radioactive forms of energy should show a parallelism to those in which light is employed as the source of energy.

As regards reactions brought about by means of the silent discharge or by Röntgen rays, the literature does not reveal a large number of examples. The formation of ozone as studied by Krüger,¹ and the decomposition of ammonia investigated by Davies,² show points of resemblance to the primary light reactions. Quite recently an investigation by Le Blanc and Volmer³ on the combination of hydrogen and chlorine under the influence of Röntgen rays shows, as regards the ratio of energy supplied to chemical reaction produced, a parallelism to the secondary light reactions. Concerning this particular research a more detailed discussion will be given later.

The literature of reactions assisted by radioactive forms of energy has been admirably collected and discussed in detail by Lind.⁴ The author

¹ Nernst, *Festschrift*, Halle, p. 240 (1912).

² *Z. physik. Chem.*, **64**, 657 (1908).

came to the conclusion that in reactions caused by alpha particles, as many molecules are brought into reaction as ions are formed in the same period of time. From a careful study of the ozonization of oxygen under the influence of alpha particles, Lind formulated an "Ionic theory of ozonization," comparable in every way with the theory of primary light reactions as developed by Bodenstein. The theory was shown to be applicable, with one exception, to the reactions caused by radioactive energy then studied. The exception to the above formulation of Lind was the combination of hydrogen and chlorine. Jorissen and Ringer¹ studied this reaction, using a radium salt as the source of energy, the measurements being made in an actinometer over water. According to the calculations of Lind, for every ion produced by the radiant energy 100 to 1000 molecules of hydrogen chloride result. It was further shown that, in this case also, as regards a period of induction and irregularity of sensitivity of the gaseous mixture, due doubtless to variation of its oxygen content, the reaction ran parallel to the photochemical change.

It appeared, therefore, probable that the combination of hydrogen and chlorine under the influence of energy from radioactive sources would prove an interesting and valuable subject for closer investigation. Owing to the development of experimental technique in late years it should be possible not only to evaluate the energy relationships of the reaction but to elucidate the kinetics of the combination.

Experimental.

The method employed in the present work is, with suitable modifications, that employed by Lind² in the study of the ozonization of oxygen.

The reaction vessel consisted of a large bulb 12 cm. in diameter into the base of which was sealed the vessel designed to hold the emanation. This consisted of a tube drawn out to a fine thin-walled capillary on the end of which was blown a small bulb approximately 1 cu. mm. vol., uniform as regards thickness of wall. The preparation of such bulbs has been very fully described by Lind³ and the same procedure was adopted in the present instance with one modification. To create the requisite pressure inside the tube during the drawing of the capillary and the blowing of the bulb, a bomb of compressed nitrogen was employed instead of the foot bellows. In this way a more uniform and more easily regulated pressure was obtained. Each bulb was tested as to strength, uniformity and range. They were tested to withstand a vacuum and an excess pressure of one atmosphere. The uniformity and range were determined by filling the bulb with radium emanation followed by measurement of the diameter of the luminescent circle produced on a zinc sulfide screen placed

¹ *Ber.*, 39, 2095 (1906).

² Wiener, *Monatshefte*, 32, 295 (1912).

³ *Loc. cit.*

at measured distances from the bulb and on all sides of it. An interval of from two to three hours intervened between the filling of the bulb and the making of the measurements, during which time the emanation comes into equilibrium with its disintegration products, in particular with Radium C, with alpha particle range 7.06 cm. in air. Finally a bulb was chosen of uniform range, averaging 5.6 cm. The determination was not effected without difficulty, as the quantity of radium available (10 mg.) was very small for securing sufficient illumination of the zinc sulfide screen.

The hydrogen and chlorine were generated in stoichiometric proportions by the electrolysis of concentrated hydrochloric acid. A vessel of 6 l. capacity was employed, the electrodes consisting of Acheson graphite rods 1 cm. in diameter, soaked in hot paraffin wax in a vacuum. These electrodes were sealed into the glass vessel with marine glue over which a thick layer of paraffin wax was poured. Through a side tube, hydrogen

chloride could be led in from time to time, whereby the exhausted hydrochloric acid could be again concentrated. The gases passed from the generator through three spiral wash-bottles, one filled with water followed by two containing concentrated sulfuric acid. They were then conducted to a gasometer in which they could be stored over concentrated sulfuric acid and from which they could be directed either to the reaction vessel or to an absorber.

The entrance to, and exit of the gases from, the reaction vessel were controlled by two platinum taps such as were employed by Bodenstein and Dux¹ in their photochemical investigations. By this means the use of tap-grease and consequent contamination of the gases with organic matter was avoided. The pressure in the reaction vessel was measured by means of the Bodenstein quartz-glass manometer attached by a quartz-in-glass ground joint to a capillary side-tube sealed into the capillary entrance tube of the vessel. The gases were led in from below and conducted out from above to the second platinum tap by means of capillary glass tubing. In this way the volume of dead space, outside the reaction-bulb itself, was reduced to a minimum.

During the reaction the gases were kept mixed by a small circular electric heater placed about 5 cm. from the base of the bulb, and against it. This ensured a slight local heating, causing an upward motion of the gases. Around the top of the bulb was placed a brass collar into which ice could be put in order to cool the gases, to bring about the downward motion. The device worked quite efficiently and caused no difficulties due to temperature variations, as was demonstrated by the perfect constancy of the pressure in the bulb over the extended periods of time intervening between successive measurements of the reaction velocity.

After leaving the reaction vessel the gases could pass by means of a four-way capillary tube in either of two directions. During the process of cleaning the apparatus by washing out with the electrolytic gases, they could be directed to an absorber. During the experiment samples could be taken in an evacuated receiver, which could be evacuated first by means of a water-pump and finally by means of a Töpler pump. The receiver was attached to the four-way capillary tube with the aid of a ground glass joint and by a suitable arrangement of glass taps the various operations could be performed. During purification the taps to the pump and the receiver were closed. During evacuation of the receiver the platinum tap and that to the absorber were closed, while as the sample was being taken the taps to the absorber and pump were closed. By momentarily opening the platinum tap to the evacuated receivers, which were about 25 cc. capacity, a sample of gas sufficient for analysis could be obtained. After each successive withdrawal of gas the pressure in the reaction vessel

¹ *Loc. cit.*

was noted. The gases were analyzed after absorption in potassium iodide solution by titration of the liberated iodine with standard thiosulfate solution and estimation of the hydrochloric acid—after expulsion of dissolved carbon dioxide by boiling—with standard baryta solution.

The emanation was obtained from 10 mg. of radium bromide. It was collected from the slightly acidified aqueous solution of the salt in an apparatus similar in every way to that described by Lind, which calls, therefore, for no further description here.

The method of purification employed was a modified form of the procedure adopted in the laboratory of Mme. Curie and described by Lind. The emanation passed from the cylinder in which it was collected, first over heated lead dichromate, copper and copper oxide, to decompose any organic impurities and to remove hydrogen and oxygen. Thence it passed over caustic potash and phosphorus pentoxide through a T-piece into a tube connecting a U-tube with the capillary and bulb sealed into the reaction vessel. The U-tube contained a length of copper wire upon which the emanation could be condensed when the tube was cooled in liquid air. Beyond the U-tube came a mercury trap followed by a MacLeod gage and Gaede mercury pump.

After evacuation of the purification apparatus, capillary and bulb to 0.0001 mm., the mercury trap was closed and the emanation allowed to pass into the purification tubes and to circulate over the heated portions and absorbents into the remaining tubes. After one to two hours the residual gas was collected in the U-tube by cooling this in liquid air, the mercury trap opened and the uncondensed gases remaining were pumped away. The glass was then sealed at the T-piece and still further evacuated to 0.0001 mm. This completed, the mercury trap was again closed and the tube between it and the MacLeod gage was sealed. By withdrawal of the liquid air and by slight warming of the U-tube, the emanation was vaporized. It was then pumped, by means of the mercury in the mercury trap, into the small emanation bulb.

Special attention is directed to Fig. 2, illustrating the arrangement of the emanation bulb. In the study of the ozonization of oxygen it was found by Lind that an uncontrollable variation of the ozone formation, for unknown reasons, could not be avoided. Such variations in the present series of measurements would render a study of the kinetics of the reaction impossible, as a reaction constant must be derived to distinguish the order of reaction. A careful examination of the experimental technique employed by Lind suggested one possible source of error, the variation of the level of mercury, at the neck of the emanation bulb due to variations in the temperature of the apparatus or of the barometric pressure. These could quite possibly be considerable, as the period of experiment varied from 12 to 24 hours. They could operate in two directions. Either

the mercury could rise into the bulb, in which case some of the alpha particles would be absorbed by the mercury and the lower portion of the apparatus being shielded by the mercury, ozonization would not occur

there; or, on the other hand, the mercury level might fall in the capillary, withdrawing the emanation partially from the bulb into the tube through the wall of which the alpha particles could not penetrate. It is difficult to imagine that these variations could alone be responsible for the considerable variations of the experimental results, but in the present series of measurements a device was employed whereby this possible source of error was eliminated.

and that changes in temperature would affect the level of mercury in the capillary. To obviate this difficulty an interesting device was employed. By inserting a piece of fused silica (whose coefficient of expansion is very low) in the open space above the ground glass joint, the greater expansi-

Immediately below the seal of the capillary in the reaction vessel a ground glass joint was attached, fitted with a tight fitting plunger which operated through a rubber band in the base of the wider tube to which the joint was sealed. The rubber band was sealed both to the wider tube and the plunger by means of marine glue and was rendered vacuum-tight by surrounding it with an outer vessel containing mercury. The emanation entered the wider tube from the purification apparatus through a tube sealed into the side. By pushing the plunger home and suitably supporting it, a mercury-tight seal could be made at the ground glass joint, while by stretching the rubber connection the joint could be opened. In actual work the mercury was brought to such a level in the capillary emanation tube that on pushing the plunger home the mercury rose just to the neck of the bulb.

In this manner influences of barometric pressure were eliminated. It is obvious, however, that with the tube closed at the ground glass joint the bulb and the mercury above the seal would functionate as a thermometer

bility of the mercury over that of the glass was corrected for. A knowledge of the rates of expansion of the three substances and of the volume occupied by the mercury in the absence of the silica enabled one to calculate the volume of silica required. In this way variations in the level of the mercury due to temperature changes were obviated and a constant level obtained. The device functioned admirably. On one occasion where for experimental reasons (see p. 20) the mercury was cooled twenty to thirty degrees, the level in the tube showed only minute variation.

Theoretical.

The processes occurring may be set forth as follows:¹

1. In the passage of an alpha particle through the gaseous mixture, ionization is produced and the chlorine molecules decompose into positively charged radicals and electrons.

2. The electrons disappear in two ways:

(a) They add on to oxygen molecules, activate these, yielding probably ozone which again forms oxygen (the function of oxygen in the photochemical reaction has been elaborately set forth by Bodenstein and in the present deductions the assumptions then made have been followed).

(b) They attach themselves to chlorine molecules, yielding the negatively charged chlorine molecules which are the material for the formation of hydrogen chloride.

3. The negatively charged chlorine molecules disappear in two ways:

(a) They regenerate neutral chlorine molecules in that their electrons neutralize themselves with the positively charged rests formed in (1), or in some other way lose their charge.

(b) They react with hydrogen to form hydrogen chloride with regeneration of the electron, which then enters upon the cyclic process again and continues thus until eliminated as postulated by (2a).

The equations representing these processes may be represented thus:

The corresponding reaction velocity equations are:

$$(1) \quad + \frac{d\ominus}{dt} = k_1 J \text{ absorbed.}$$

In the experimental conditions chosen, all the alpha particles are absorbed and so

$$+ \frac{d\ominus}{dt} = k_2 J \quad (A)$$

¹ Cf. Bodenstein, *Loc. cit.*, p. 346, *et seq.*

where J is the radiant energy employed.

$$(2a \text{ and } b) - \frac{d\ominus}{dt} = k_4[\ominus][O_2] + k_5[\ominus][Cl_2].$$

On attainment of equilibrium conditions,

$$+ \frac{d\ominus}{dt} = - \frac{d\ominus}{dt}$$

+ $\frac{u\ominus}{dt}$ is composite, being determined by reaction Equation A and the process of regeneration of electrons detailed in (3b). This latter is identical with, and is, therefore, equal to,

$$k_8 [Cl_2^-] [H_2].$$

Assuming that each Cl_2^- formed combined instantaneously with H_2 we have

$$+ \frac{d[2HCl]}{dt} = + \frac{d[Cl_2^-]}{dt} = k_5[\ominus] [Cl_2] \quad (B)$$

Therefore

$$+ \frac{d\ominus}{dt} = k_2 J + k_5[\ominus] [Cl_2]$$

and so

$$k_2 J + k_5[\ominus] [Cl_2] = k_4[\ominus] [O_2] + k_5[\ominus] [Cl_2]$$

Whence

$$[\ominus] = \frac{k_2 J}{k_4[O_2]}.$$

From (B), therefore, we get

$$+ \frac{d[Cl_2^-]}{dt} = \frac{d[2HCl]}{dt} = k_2 \frac{k_5}{k_4} \cdot \frac{J[Cl_2]}{[O_2]}$$

a reaction velocity equation of the first order, derived with the assumption that the formation of hydrogen chloride results from the combination of negatively charged molecules of chlorine with hydrogen molecules and that this combination is instantaneous. Were this not the case, a consideration of the reaction equations will show that, if both hydrogen and chlorine were involved in the electronic processes, the formation of hydrogen chloride would yield a velocity equation of the second order.

The experimental results presented below offer a justification for the viewpoint adopted. Column 1 gives the times, in hours, at which measurements were made. In the second column are recorded the pressures. Columns 3 and 4 give the titers of chlorine and hydrochloric acid, respectively. To ensure greater accuracy, the acid titer was made with a more dilute solution (normality of baryta solution, one-third the normality of the thiosulfate solution) than was employed for the titration of the iodine, but in the tables they are presented in equivalent units. Column 5 gives the total volume of hydrogen, chlorine and hydrogen chloride in the same

units, whence the actual volumes in millimeters of mercury presented in Columns 6 and 7 could be calculated. Columns 8 and 9 give $d[2\text{HCl}]$ and dt , respectively, while Column 10 gives the reaction constant k_a calculated from point to point for the simple differential equation

$$+ \frac{d[2\text{HCl}]}{dt} = k_a[\text{Cl}_2].$$

Column 11 gives the correction-factor E for the decay of emanation calculated from the equation

$$\text{Log } E = \frac{\text{Log } E \text{ at time } t + \text{Log } E \text{ at time } t + dt}{2}$$

assuming the initial factor for E to be 100. Column 12 gives the values (k_b) after the introduction of this correction in (k_a). Hence the differential equation employed in this column may be written thus:

$$+ \frac{d[2\text{HCl}]}{dt} = k_b E [\text{Cl}_2]$$

Column 13 gives the value (k_c) of (k_b) multiplied by the pressure during the given time interval. The reason for this is obvious. Since samples are constantly withdrawn for analysis it is obvious that the oxygen concentration also undergoes constant diminution in amount proportional to the volume of gas withdrawn. The equation is, therefore:

$$+ \frac{d[2\text{HCl}]}{dt} = k_c E \frac{[\text{Cl}_2]}{\text{Total Pressure, } P}$$

whence it follows that:

$$\frac{k_c}{P} = k_2 \frac{k_5}{k_4} \cdot \frac{1}{[\text{O}_2]}$$

as derived in the theoretical portion of this paper.

The hydrogen and chlorine were passed into the evacuated reaction vessel from the gasometer two to three hours after the bulb was filled with emanation. The gases were analyzed immediately in all except the first experiment, Table I, in which case the first analysis ($t = 0$) was made one hour after filling. The experiments were carried out, naturally, in a dark room illuminated by the light of a single carbon filament lamp enclosed in a yellow covering. The reaction vessel was further protected against illumination by a covering of thick black paper.

The results of the four experiments are given in Tables I to IV.

It is evident that in the initial stages of the reaction a period of induction was present. This was doubtless due to impurities in the reaction vessel caused by a modification of the apparatus a day or two previous to the commencement of the experiments. The time available for the completion of the work did not permit of an elimination of this by extended cleansing of the apparatus with the electrolytic gases. Conse-

quently, the induction period was also found in the two following series. In the fourth series this influence seems to have disappeared.

A rough test of the reactivity of the gases towards light showed that, although reactive, they were by no means comparable in activity with the gases employed by Bodenstein and Dux. The cause for this lay doubtlessly in the exhaustion of the hydrochloric acid from which the gases were produced.

The last value in Table III is of interest in view of the remarks made previously as to the importance of maintaining the mercury at a constant level in the emanation bulb tube. The sudden fall in the constant k_c

of the last measurement could not be accounted for until an observation of the reaction vessel showed that from some unknown cause (probably a release at the ground glass joint) the mercury level had fallen a centimeter or so in the capillary withdrawing, therefore, some of the emanation from the bulb, and so decreasing the energy factor E in the equation.

At such low pressures as are reached in the later measurements of Expt. 3 (pressures 303 and 294 mm.) it is obvious that the absorption of the alpha particles cannot be regarded as complete, and the value found for k_c is low. To avoid a correction for incomplete absorption and yet at the same time obtain an extended range of pressure variation, Expt. 4 was performed. The residual gases from Expt. 3 were left in the reaction vessel, which was then cooled in a mixture of solid carbon dioxide and acetone. Fresh hydrogen and chlorine were led into the vessel from the gasometer until it was full at the prevailing temperature. The taps were then closed and the cooling mixture removed. On the attainment of room temperature it is clear that the reaction vessel was filled with a hydrogen, chlorine, hydrochloric acid mixture at more than atmospheric pressure. It was during this operation that the contrivance for maintaining a constant mercury level in the capillary emanation tube was shown to functionate so well; for at the low temperature attained (about -20° , as calculated from the pressure measurement) the contraction in volume of the mercury was quite small.

Discussion of the Results.

The constancy of the values tabulated in the last column, k_c , of the several tables permits of the following conclusions being drawn:

1. The combination of hydrogen and chlorine under the influence of alpha particles is a reaction of the first order. As the hydrogen and chlorine are present in equivalent amounts it is not possible to state definitely from the results that the reaction is proportional to the chlorine concentration, though this is probably the case. This point could only be established by variation of the ratios of hydrogen to chlorine employed.
2. The hydrochloric acid formed is without influence on the velocity.
3. Oxygen retards the reaction, such that the velocity at all stages of the decomposition is inversely proportional to the oxygen concentration.
4. The experimental facts may be interpreted by means of a reaction velocity equation:

$$+ \frac{d[2\text{HCl}]}{dt} = k J \frac{[\text{Cl}_2]}{[\text{O}_2]}$$

It will, therefore, be seen that, as regards the kinetics of the combination, the reaction shows complete parallelism to the photochemical reaction. The point of divergence in the two velocity equations, *viz.*, the power of the chlorine concentration, is readily explainable by the fact that in the one case absorption of the available energy is complete and in the other quite small.

As regards parallelism between the ratios of energy absorbed to reaction produced, unfortunately, little can be said from the present work. The condition of affairs prevailing in Central Europe prevented a con-

tinuance of the work in the direction of more reactive gases and determination of the amount of radioactive energy employed. In this connection, however, the calculations of Lind from the results of Jorissen and Ringer tend to show that for each ion produced by the radiant energy 100 to 1000 molecules of hydrogen chloride are formed. Also, it must be remembered that the amount of oxygen present in the gaseous mixture exercises a profound influence on the energy ratio, as the present results and those of Chapman and Bodenstein show. For, it follows as a natural consequence of the reaction velocity equation developed, that in gases of absolute purity the reaction would be infinitely rapid; that is, a small quantity of energy would suffice to bring about an infinitely large combination of the gases. This conclusion is confirmed in the observation that extremely pure gases tend so easily to explode.

The point should be especially borne in mind when drawing conclusions such as were recently drawn by Le Blanc and Volmer.¹ The energy ratio required in the light reaction according to the calculations of these authors, *viz.*, that one electron must catalyze at least 10^{12} molecules, would easily be realized in an explosive mixture of the gases. Also, with regard to the further suggested proof which the authors bring forward—namely, that Röntgen rays bring about combination, but that in their gas mixture, at the most 10^4 molecules combine as a result of the liberation of one electron or ion—it must be recognized that such proof cannot be regarded as sound if, as seems very probable from analogy with the present communication, oxygen retards the rate of reaction. The authors mention further that their experimental conclusions do not exclude the possibility of the hydrogen-chlorine combination taking place through a loosening (*Lockering*) of the electrons such as was postulated by Stark. This observation overlooks one consequence of the theory of Stark, already emphasized by Bodenstein,² “*der Fall, dass mehr als eine Molekel durch ein Quantum umgesetzt werden kann, ist bei Starks Darlegungen überhaupt nicht vorgesehen.*” As their results show, 10^4 molecules combine due to one ion.

It is evident, therefore, that an extension of this field of work with a view to determining the kinetics of the hydrogen-chlorine combination under the influence of Röntgen rays would not fail to be of interest. Also, an exact evaluation of the energy employed to chemical reaction produced, with a gas of *constant* composition, under the three influences, light, radioactive energy, and Röntgen rays, should be invaluable for the gaining of a closer insight into the reaction mechanism.

Summary.

The kinetics of the combination of hydrogen and chlorine under the influence of the alpha particles from radium emanation has been studied.

¹ *Loc. cit.*

² *Ibid.*, p. 394.

The technique of such radioactive investigations has been improved with a view to giving greater constancy of experimental conditions.

The reaction has been shown to be one of the first order, in agreement with a theory developed, whereby the velocity of formation of hydrochloric acid should be proportional to the energy employed and to the chlorine concentration, inversely proportional to the oxygen concentration.

The analogy between the photochemical reaction and the reaction studied has been emphasized and the bearing of the experimental results on the problem of the photochemical and Röntgen ray reactions has been discussed.

The experimental work of the preceding paper was carried out in the Koenigliche Technische Hochschule zu Hannover. To Professor Max Bodenstein, at whose suggestion the research was undertaken, the author wishes to express his deep indebtedness, as well for the generous advice and kindly interest as for the many details of experimental technique which made the work possible.

THE DENSITIES AND DEGREES OF DISSOCIATION OF THE SATURATED VAPORS OF THE AMMONIUM HALIDES, AND THE RELATED THERMAL DATA.

BY ALEXANDER SMITH AND ROBERT H. LOMBARD.

Received November 13, 1914.

In the case of solids undergoing thermal dissociation the data which possess the greatest chemical significance are those relating to the *saturated* vapors, in which the components of the vapor are in equilibrium with each other and with the solid. Yet, in regard to the great majority of even the most familiar of such substances, as, for example, phosphorus pentachloride and the ammonium halides, definite, quantitative information in this direction has been absolutely lacking. The vapor (dissociation) pressures have been determined, sometimes repeatedly, but for the most part the densities of the unsaturated vapors (namely, at atmospheric pressure) have alone been measured. Of the very few systems involving saturated vapors which have been subjected to exact study, those of the sulfides of ammonium (Isambert and others) and calomel (Smith and Menzies¹) may be mentioned.

As regards the ammonium halides, their dissociation pressures had not been determined with the requisite degree of accuracy. To secure consistent values for use in the present investigation, these pressures have

¹ THIS JOURNAL, 32, 1541 (1910); Z. physik. Chem., 76, 251.

been redetermined by Smith and Calvert,¹ using a thermometer identical with that employed in the present work, a bath similarly jacketted but smaller, and the same samples of the ammonium halides.

As regards the vapor densities of the ammonium halides, it is commonly assumed by chemists that the dissociation is complete, and that the densities correspond with this assumption. Only the comparatively easily measured densities of the *unsaturated* vapors have been determined, however, and the results of the present work show that this assumption is very far from being correct. In the present research the densities of the saturated vapors of the ammonium halides have been investigated. The results, together with the corresponding dissociation pressures of Smith and Calvert, have made it possible now to ascertain by calculation, and to give for these substances the values of the degrees of dissociation, the dissociation constants, the partial pressures of the dissociation products, the heats of dissociation, and the latent heats of vaporization.

Previous Determinations of the Vapor Densities.—In Table I the results of previous determinations are given. The methods used (Col. 2) are indicated thus: D. (Dumas), H. (Hofmann), V. M. (V. Meyer). The temperature (Col. 3) is the value assumed by the observer. The heating was effected by the vapor of the substance indicated in Col. 4, boiling (save in one instance) under the existing atmospheric pressure. The actual temperatures obtainable with the vapors of these substances vary considerably with the existing atmospheric pressure, yet Ramsay and Young are the only observers who corrected the boiling point of the bath liquid on this account. The actual temperatures obtainable vary still more (5° to 8° or more) according as much, little, or no jacketing is used. None of the observers mention jacketing and presumably they used none. The recorded temperatures must therefore be, for the most part, considerably higher than those actually attained.

For the purpose of comparison, the observed vapor densities (Col. 5), originally given on such scales as air = 1, hydrogen = 1, or mols per liter, have all been re-calculated to weights of 1 cc. at 0° and 760 mm. The calculated values for the density, assuming no dissociation (δ) are given for each substance after its name. The per cent. dissociated (Col. 6) has been calculated from the values of δ , and of Δ (Col. 5).

Discussion of Previous Determinations.²—Where the Dumas method is used, the temperatures, for the reason already given, are only approximate. Then, at 357° the dissociation pressure of ammonium chloride is about 1150 mm., so that, at 760 mm. in the open Dumas bulb at this temperature, the vapor has reached a highly unsaturated condition,

and dissociation has been favored. The fact, therefore, that values indicating 91–100% dissociation are thus obtained, does not prove that the vapor when saturated is dissociated to this extent. Similarly, in the case of ammonium bromide, a dissociation pressure of 760 mm. is reached at 394.6°, and at 445° the pressure is over 2 atmos. With ammonium iodide 760 mm. pressure is reached at 405°, and at 445° the pressure is about 2 atmos. These vapors were therefore also under greatly reduced

pressure, and the observations afford no information in regard to their degree of dissociation when saturated.

Where the Victor Meyer method was used there were two possibilities. In the first four observations of Pullinger and Gardner, in the observations of Neuberg (made under 25 mm. pressure) and in those of Gutmann, the temperature was such that the substance exercised a dissociation pressure greatly exceeding that finally existing in the apparatus. In these instances, therefore, the vapor became highly unsaturated and dissociation was favored. In the last three observations of P. and G. the dissociation pressure at 300° (252.5 mm.) was not sufficient to permit rapid vaporization and free displacement of the air (at 760 mm.). Here, therefore, the vaporization would proceed largely by diffusion of the gases into the air contained in the apparatus. Naturally, dissociation was promoted by this process of diffusion, and the displacement of air could stop only when dissociation was complete. Strictly speaking, the same thing is true of all determinations by the V. Meyer method. Every substance capable of dissociating, no matter how slightly, would be bound by this method to yield a value for the density corresponding to complete dissociation. If these observations had shown 100% dissociation, they would only have proved that the laws of equilibrium were at work, and would have given no new information about the properties of ammonium chloride.¹ Since the P. and G. determinations, for example, gave only 87% dissociation, what they did prove was that the method was inaccurate (densities 7% too low) under these conditions. The results by these two methods, apart from the obvious crudeness of the measurements, are therefore valueless for a study of the state of equilibrium in the system, because the conditions are wholly indefinite.

In the method used by F. M. G. Johnson and Abegg, the solid salt was contained in the smaller of two connected bulbs, both of which were completely evacuated. The bulbs were heated in an air bath, the larger bulb was then sealed off, and its volume and content of ammonium chloride determined. This method would have given the density of the saturated vapor, if both bulbs had been at the same temperature. But that containing the solid was intentionally kept at a temperature about 22° below that of the bulb containing the vapor. Hence, this result also applies to the unsaturated vapor, and no information about the density of the saturated vapor is obtainable from the data.

Finally, the observations of Ramsay and Young were made by the Hofmann method. They made nine determinations at 280° with pres-

¹ The fact that the facile V. Meyer method is applicable indeed to the detection of the existence of dissociation (if this has not been detected otherwise already), but is valueless for the study of the extent of such dissociation, seems to have been too generally overlooked.

tures varying from 127.3 mm. to 134.9 mm. The values quoted in the table are those obtained at these two pressures, respectively. Now the dissociation pressure at 280° is 135.0 mm., so that the last observation does yield a value for the saturated vapor. Furthermore, the observations are fairly consistent, and clearly are not in error to the extent of 20%. This observation alone, therefore, of all the published results, affords rather definite information about the density of ammonium chloride vapor in the saturated condition, and indicates that the vapor is far from being completely dissociated.

An examination of the degrees of dissociation, showing that nearly all approach 100%, within the rather wide limits of error of the methods, explains the fact that chemists have very generally accepted the erroneous conclusion that the ammonium halides are completely dissociated, and have used this incorrect assumption, for example, in calculating the heats of vaporization¹ to form saturated vapor.

Method and Apparatus.

The Vapor Density Bulbs.²—The vapor densities were determined in bulbs of the type shown in Fig. 1. A weighed amount of the substance was placed in the small bulb, A, which was then sealed on to the large bulb, B, at C. The whole was then evacuated to less than 0.01 mm. on

Fig. 1.—Vapor density bulbs.

a mercury pump, and sealed off from the pump at E. The evacuated bulb was next wired to a long iron rod, and then plunged into a well stirred bath having the desired temperature. Local cooling and cracking of the

² Essentially the same method has been previously used by Smith and Menzies (*THIS JOURNAL*, **32**, 1550 (1910)) for determining the density of saturated calomel vapor.

bulb by contact with the cold iron rod were prevented by wrapping the latter with several layers of asbestos paper. When equilibrium had been reached, the large and small bulbs were sealed and separated by raising the bulb until the arched capillary just appeared above the surface of the bath and applying the blow pipe flame to it. The amount of substance which had vaporized into the large bulb was given by the difference between the amount remaining in the small bulb, and that originally put into it. The volume of the large bulb, at the temperature at which the vapor density was measured, was determined by weighing it, first evacuated and then full of water of known temperature, and finally correcting for the expansion of the glass by using the coefficient of cubical expansion, 0.000031.

Bulb No. 1 was the first type tried, and was used for determining the vapor density of ammonium chloride. The results obtained with it had an accuracy of only $\pm 2-3\%$. Hence, in the case of ammonium bromide, the vapor density of which was next measured, a more compact form of bulb, No. 2, was used, it being thought that there would be less possibility of a difference in temperature between the extreme parts of the bulb. This change, however, did not very much increase the uniformity of the results. With ammonium iodide, Bulb No. 2, gave results so erratic as to be of almost no value. The particles of the salt had a tendency to jump about, and the irregularities were in part due to the carrying over into the large bulb of solid particles of the salt by the ammonium iodide vapor when vaporization first began. To minimize this possibility, Bulb No. 3, which contained a trap T placed between the large and small bulbs, was designed. Glass wool inserted at the same place would also serve the purpose, but would necessitate determining the amount of substance in the large bulb by analysis. The results obtained with ammonium iodide with this trap were very much less erratic than without it. It may be said here that, to determine vapor densities of solids with moderate accuracy, extreme care must be exercised. Even with such care, an erratic and unaccountable result is occasionally obtained, as the results given later will show.

The Bath.—The bath was a pressed steel "oyster bucket," 18 cm. in diameter and 23 cm. deep, filled with a 50% mixture of fused sodium and potassium nitrates. Its sides were lagged by a two-inch thickness of shredded asbestos pipe-covering, and the top was covered by a sheet of $\frac{1}{2}$ " asbestos board with openings in it for the vapor-density bulb, stirrers, and thermometer. The temperature of the bath, which was heated by a Vulcan gas burner, was kept constant within $\pm 0.2-0.3^\circ$ by the constant manipulation of a screw clamp on the gas supply tube. Two stirrers of the type described by Smith and Menzies¹ were used, each rapidly

¹ Smith and Menzies, *THIS JOURNAL*, 32, 1421 (1910).

driven by an electric motor. The vapor-density bulb was in the center of the bath, the stirrers on diametrically opposite sides of the bulb, and the thermometer directly behind the bulb.

Measurement of the Temperature.—The temperature of the bath was measured by a fused quartz, platinum resistance thermometer of the Heraeus type¹ without compensating leads. The resistance of the thermometer was measured by a dial Wheatstone bridge (5 dials), and a D'Arsonval galvanometer, both manufactured by the Leeds & Northrup Co.

The thermometer was calibrated, by the method recommended by Waidner and Burgess,² at the melting point of ice, and at the boiling points of water and of sulfur (444.7°). The steam point was determined in a glass tube 5 cm. in diameter, and 46 cm. long, heated by a Vulcan gas burner, and lagged by a conical asbestos jacket 2 cm. thick at the top, 6 cm. thick at the bottom, and 32 cm. high. The depth of water in the tube was about 10–12 cm., the bottom of the thermometer was about 4 cm. above the surface of the water, and glass beads were used to prevent bumping. An aluminum radiation shield, of the type recommended by Waidner and Burgess, was used. The sulfur boiling point tube was of brass, 4.7 cm. in diameter, and 47 cm. long. A depth of 10–12 cm. of sulfur were used, and the end of the thermometer was placed about 4 cm. above the surface of the boiling sulfur. Two mica windows at the top of the tube made it possible to observe the point of condensation of the sulfur vapor. This was kept about half way between the top of the tube and the top of the jacket. The asbestos insulating jacket and aluminum radiation shield described above were used.

In order to test the accuracy of the calibration, the boiling point of naphthalene was determined several times. The results were usually about 0.2° higher than the value given by Waidner and Burgess.³ This is probably as good a result as could be expected without using compensating leads. The constants of the thermometer increased gradually during the investigation, but the change was followed closely, and new values were adopted as soon as the difference became great enough to cause an error of as much as 0.1–0.2° in the temperature measurement. The accuracy and constancy of the temperature of the bath is estimated to have been about $\pm 0.2\text{--}0.3^\circ$.

Ammonium Chloride.

The Data.—The ammonium chloride was recrystallized once from distilled water, dried at 110°, finely ground, and kept in a desiccator over

¹ Waidner and Burgess, "The Measurement of High Temperatures" (Wiley, 3rd ed.) 205.

² Waidner and Burgess, *Bull. Bur. Standards*, 6, 150 (1910).

³ *Ibid.*, 7, 4 (1910).

phosphorus pentoxide. The vapor density was determined at ten-degree intervals from 280° to 330° , the first temperature being that at which the vapor density becomes large enough to be accurately measured, and the second that at which the dissociation pressure becomes almost equal to atmospheric pressure. The pressure of the ammonium chloride vapor in the bulb must not be allowed to become greater than atmospheric because, if it did, the capillary tube between the large and small bulbs would blow out instead of collapsing, when the two bulbs were sealed apart.

In order to obtain a final, mean result which was sufficiently accurate, it was necessary to make a number of determinations at each temperature. In order that the degree of accuracy of the measurements may be clearly seen, the results of all the determinations made are given (Table II). The volumes (Col. 3 of the table) are at the temperature at which the vapor density determination was made. The column entitled "deviation from mean" contains the difference between the average value of the vapor density and the individual measurements. Occasionally a vapor density would be obtained which was so far from the average value that we have felt justified in rejecting it. Such values are printed in italics. The precision of the average value at each temperature was obtained by averaging the "deviations from the mean," and then dividing the average by the square root of the number of observations. It will be seen that the final results usually have an accuracy of about $\pm 2-3\%$.

In Table III are summarized the vapor density results in the form in which they were used in the calculations. The vapor pressures given in this table are those determined by Smith and Calvert.¹ The method for, and the purpose of determining the "interpolated" values given in the fifth column will be explained when the calculation of the dissociation

¹ Smith and Calvert, *THIS JOURNAL*, 36, 1373 (1914).

constants is discussed. The densities, δ_m , which the vapor would have if it were undissociated (expressed in mols per liter), and yet gave the measured dissociation pressures were calculated by the formula

$$\delta_m = \frac{1}{22.4} \cdot \frac{273}{T} \cdot \frac{P}{760}$$

These values are given in the column headed, "undissociated." In the column headed, "completely dissociated," are the densities which the vapor would have if it were wholly dissociated and gave the measured dissociation pressure. These values are just one-half of the corresponding "undissociated" vapor densities.

In order to show the relation between the measured vapor density and the density of the vapor if it were completely dissociated, and if undissociated, these values have been plotted in Fig. 2. The fact that

Fig. 2.—Vapor densities of ammonium chloride: Curve I—Undissociated (calculated); Curve II—Observed; Curve III—Completely dissociated (calculated).

the experimentally determined values lie between the "undissociated" and the "completely dissociated" densities, shows conclusively that saturated ammonium chloride vapor is not completely dissociated. If it were completely dissociated, the measured values would lie, at least approximately, on the "completely dissociated" curve.

The Degrees of Dissociation.—In calculating the degree of dissociation of ammonium chloride vapor, it was assumed that the equilibrium present in the vapor is represented by the equation

and that the gases follow the laws of perfect gases. If so, the degree of dissociation α is given by the formula

$$\alpha = \frac{\delta_m - \Delta_m}{\Delta_m}.$$

In this formula, δ_m , and Δ_m , are respectively the "undissociated," and the observed molar vapor densities (Table III). The degrees of dissociation thus calculated are given in Table IV (Col. 2).

TABLE IV.— NH_4Cl —DEGREES OF DISSOCIATION.

Temp. C.	Percentage dissociation.		Deviation of α from straight line.		% error in α . (Calcd.)
	Obsd.	Interpol.	Actual.	%.	
280	55.5	66.8
290	67.1	66.0	+1.1	+1.7	± 4.5
300	64.2	65.2	-1.0	-1.5	± 5.5
310	63.8	64.4	-0.6	-0.93	± 3.5
320	63.3	63.6	-0.3	-0.47	± 1.8
330	63.6	62.8	+0.8	+1.3	± 3.3

Inasmuch as the measured results are somewhat irregular,¹ the relation between the degree of dissociation and the temperature is seen best from the graphic representation of the results given by Fig. 3, Curve I. This curve shows that between 280° and 330° , saturated ammonium chloride vapor is 67–63% dissociated; and that, although the degree of dissociation is very nearly constant, it apparently decreases slightly and, as nearly

¹ The irregularities in our results might be attributed to adsorption of the vapors by the surface of the bulbs, or might be connected with the existence of transition points for ammonium chloride and bromide at 159° and 109° , respectively (Wallace, *Chem. Zentr.*, 81, 727 (1910)). In view of the fact that our measurements were made at relatively high temperatures, usually 300° and above, these explanations must be discarded.

as can be judged, linearly with the temperature. In view of the irregularity of the measured values of α , we shall use hereafter in any calculations which involve α , values interpolated from Curve I in Fig. 3. These values are given in the third column of Table IV.

Fig. 3.—Percentage dissociation of saturated ammonium chloride and bromide vapors: Curve I—Ammonium chloride; Curve II—Ammonium bromide.

The irregularity of α is not, however, more than might be expected, because the relation between α and Δ_m is of such a nature that an error in Δ_m is multiplied several times in α . To illustrate this, we give the errors in the values of α which might be expected, and compare these with the actual errors. The error in α which would be caused by an error in Δ_m may be calculated as follows: If $d\Delta_m$ is the error in Δ_m , the error in α , will be,

$$\frac{\partial \alpha}{\partial \Delta_m} d\Delta_m = \frac{\partial}{\partial \Delta_m} \left[\frac{\delta_m - \Delta_m}{\Delta_m} \right] d\Delta_m = -\frac{\delta_m}{\Delta_m^2} d\Delta_m,$$

and the percentage error in α will be,

$$\frac{\partial \alpha / \partial \Delta_m d\Delta_m}{\alpha} = \frac{-\delta_m / \Delta_m^2 d\Delta_m}{\delta_m - \Delta_m / \Delta_m} = -\frac{\delta_m}{\delta_m - \Delta_m} \frac{d\Delta_m}{\Delta_m}$$

But $\frac{d\Delta_m}{\Delta_m}$ is the percentage error in Δ_m . Therefore,

$$(\% \text{ error in } \alpha) = -(\% \text{ error in } \Delta_m) \frac{\delta_m}{\delta_m - \Delta_m}.$$

In the sixth column of Table IV are given the percentage errors in α , calculated by this equation, which would result from the percentage errors in Δ_m which are given in Table II. The actual errors in α , *i. e.*, the deviation of the observed values of α from the average values, are

given by the difference between the observed values of α and the value interpolated from the straight line. These differences are given in the fourth column of Table IV, and the fifth column contains these differences expressed as percentages of the observed value of α . Comparison of Columns 5 and 6 shows that the percentage deviation of α from a straight line is much less than might be expected to result from the errors in Δ_m . Therefore, a straight line represents the relation between the degree of dissociation and the temperature within the experimental error of the observations. The value of α at 280° , which is obviously too low, was not considered when the best representative straight line was drawn.

The fact that the vapor density increases and that the degree of dissociation *diminishes* with rising temperature, is at first sight anomalous. It must be remembered, however, that the results are not obtained with constant total pressure (as in the Dumas and V. Meyer methods) but with rapidly rising total pressure (vapor pressure). Thus between 290° and 330° the partial pressure of free ammonia (or HCl, see Table XV) rises from 73.7 mm. to 234.5 mm., while the total pressure increases from 185.3 mm. to 610.6 mm., or almost in the same proportion. If we calculate the change in partial pressure of free ammonia which would occur between the same limits of temperature if the total pressure were kept constantly at 185.3 mm., we find that this partial pressure would rise from 73.7 to 83.6 mm. Thus at a constant pressure of 185.3 mm., the density would diminish and the degree of dissociation would *increase* from 66% to 82%.

The Latent Heat of Vaporization.—Several determinations of the latent heat of vaporization of ammonium chloride have previously been attempted, but none of them gives the true latent heat of vaporization, namely, the heat-change involved when ammonium chloride vaporizes in equilibrium with the products of its vaporization. These previous determinations are summarized in Table V.

TABLE V.— NH_4Cl —LATENT HEATS OF VAPORIZATION (Kg. cal. per mol).

¹ Marignac, Liebig's *Ann.*, **149**, 351 (1869).

² Horstmann, *Ber.*, **2**, 137 (1869).

³ F. M. G. Johnson, *Z. physik. Chem.*, **65**, 38 (1908-9); Favre and Silbermann (*Ann. chim. phys.*, [3] **37**, 422 (1853)), and J. Thomsen (*Thermochem. Untersuch.*, Leipzig, Band II, 73-75 (1889)) have found the values 39.7 and 41.3, respectively, for the heat of reaction between ammonia and hydrogen chloride

Horstmann and F. M. G. Johnson calculated the latent heat of vaporization from their respective vapor pressure data, the former using the Clausius-Clapeyron equation, and the latter the relation, $d \ln p/dT = Q/2RT^2$. Both, however, made the incorrect assumption that saturated ammonium chloride vapor is completely dissociated. Hence, their results must be larger than the correct values.

Marignac's experimental method was admittedly rather inaccurate, the measurements were made at atmospheric pressure, and the value for the latent heat of vaporization given in Table V is the mean of two extreme values, 33.0 and 43.8. Since his measurements were not made under equilibrium conditions, the results have little quantitative significance.

Previous observers have, therefore, failed to obtain correct values for the latent heat of vaporization of ammonium chloride, either because they have not worked under equilibrium conditions, or because, in the absence of data in regard to the densities of the saturated vapor, they have uncritically assumed complete dissociation.

Neither of these objections, however, applies to the method which we have used, because we have calculated the molar latent heat of vaporization from the dissociation pressures and the saturated vapor densities, using the Clausius-Clapeyron equation, $L = T \partial P/\partial T (V - v)$. In this equation, v , the molar volume of the solid, is negligible; and the molar volume of the vapor V is equal to $1/\Delta_{mi}$. The value of $\partial P/\partial T$ was found from the Kirchoff-Rankin-Dupré equation

$$\log P = -A/T + B \log T + C,$$

in which the constants, A , B , and C have been evaluated for the ammonium halides by Smith and Calvert.¹ When this equation is solved for P , and the resulting value of P is differentiated with respect to T , it is found that,

$$\frac{\partial P}{\partial T} = P \left[\frac{A}{0.4343 T^2} + \frac{B}{T} \right].$$

Substituting now in the Clausius-Clapeyron equation these expressions for V , and $\partial P/\partial T$ gives

$$L = T \frac{P}{760} \left[\frac{A}{0.4343 T^2} + \frac{B}{T} \right] \frac{0.02419}{\Delta_{mi}} \text{ Kg. cal.}$$

P is the dissociation pressure of ammonium chloride in mm. of mercury, and Δ_{mi} is the interpolated molar vapor density, both as given in Table III., $A = 1920$, and $B = 9.779$.

at room temperature. Johnson incorrectly quotes these data as heats of vaporization, and compares his values of the latent heat of vaporization with them.

¹ Smith and Calvert, *THIS JOURNAL*, 36, 1368, 1371, 1373 (1914).

Using this formula, the following values of the molar latent heats of vaporization between 280° and 330° were obtained:

NH ₄ Cl—LATENT HEATS OF VAPORIZATION (Kg. cal. per mol).					
280°	290°	300°	310°	320°	330°
32.5	32.7	32.9	33.0	33.2	33.3
Average value.....		32.9			

Since the extreme values differ only by about 1% from the average value, it may be assumed that the latent heat of vaporization of ammonium chloride between 280° and 330° is constant within the experimental error. That the average value is smaller than the older values given in Table V is to be expected, because, as explained above, the latter were obtained by methods which would necessarily yield results larger than the correct value.

The Dissociation Constant.—For calculating the heats of dissociation, it is necessary to determine the dissociation constants of ammonium chloride at different temperatures. The dissociation constant K_c is given

by the equation

$$K_c = \frac{\alpha^2}{1-\alpha} \Delta_{mi}.$$

First, a series of values of K_c was calculated, using the observed molar vapor densities Δ_m (Table III), and the observed values of α (Table IV). The values of the dissociation constant thus determined are the "observed" values given in Table VI, and they are represented graphically by the points which lie on either side of the curve in Fig. 4. They are, of course, somewhat irregular because of the experimental errors in Δ_m and, especially, in α .

Fig. 4.—Dissociation constants of saturated ammonium chloride vapor.

In order to get a smooth, average set of values of K_c , a second series of values was calculated,

using the interpolated values of α , given in Table IV, and the "interpolated" vapor densities, Δ_{mi} (Table III). Δ_{mi} was calculated by the formula

$$\Delta_{mi} = \frac{\delta}{1 + \alpha_{interpol.}},$$

and is simply the density which the saturated vapor would have if it gave the interpolated values of α instead of the measured values. This second series of values of K_c is that entitled "average" in Table VI, and they lie directly on the curve in Fig. 4.

TABLE VI.— NH_4Cl —DISSOCIATION CONSTANTS— K_c .

Temp.	280°.	290°.	300°.	310°.	320°.	330°.
Observed.....	0.00174	0.00432	0.00496	0.00644	0.00828	0.0110
Average.....	0.00316	0.00407	0.00523	0.00665	0.00842	0.0106

The difference between the observed and the "average" values of K_c is, in some cases, rather large, but not greater than would be expected from the nature of the relation between K_c and α , and the error in α . Fig. 4 shows that the "average" values of K_c , as represented by the curve, are the best possible average of the observed values. These "average" values of K_c will be used in calculating the heat of dissociation rather than the observed values.

The Heat of Dissociation—General.—The fundamental relation between the heat evolved during dissociation, and the dissociation constant is expressed by the van't Hoff equation

$$\frac{d \ln K_c}{dT} = - \frac{U}{RT^2}.$$

U is the heat which would be evolved if one mol of substance, *e. g.*, ammonium chloride vapor, dissociated isothermally, without performing external work. In order to integrate this equation it is necessary to decide upon the nature of the relation between U and T . The exact relation not being known, it has been customary to employ an interpolation formula of the type

$$U = A + BT + CT^2 + DT^3 + \dots \quad (\text{I})$$

where A, B, C, D, \dots are constants. Lundén,¹ in the calculation of heats of ionization, has used the condensed form,

$$U = A + BT, \quad (\text{II})$$

disregarding powers of T higher than the first. This, however, is not in agreement with Nernst's heat theorem, which postulates the relation,

$$dU_0/dT = \text{zero.} \quad (U_0 = U \text{ at absolute zero.})$$

The equation used by Lundén gives $dU_0/dT = B$. Hence, it is evident that in Equation I above, $B = \text{zero}$.

¹ Lundén, *J. chim. phys.*, 5, 593 (1907).

The representation of U in expanding powers of T has recently been studied by Arrhenius.¹ We have, from the second law of thermodynamics,

$$U = A - TdA/dT \quad (A = \text{free energy}).$$

Hence, if we assume A represented in expanding powers of T , *i. e.*,

$$A = A_0 + BT + CT^2 + DT^3 + \dots$$

we have also,

$$T dA/dT = BT + 2CT^2 + 3DT^3 + \dots$$

and consequently, by subtraction,

$$U = A_0 - CT^2 - 2DT^3 - \dots \quad (\text{III})$$

Now Arrhenius has shown that in this equation, if we do not consider very high temperatures, all powers of T above the second may be disregarded. The resultant equation,

$$U = A_0 - CT^2$$

is very widely applicable, and has been proved to hold for many different types of reactions through large ranges of temperature. Nevertheless, it must always be carefully borne in mind that the equation is, in the end, only an approximation, being a condensed form of the expanding series shown in (III), and breaking down if its limits are overstepped. Strictly speaking, the equation is also dependent upon the gas laws, and should be applied only if they hold exactly. The practical range, however, is much wider, and it can be used with success in many cases where the gas laws do not even approximately apply. In such instances it must be considered to be merely an interpolation formula, and in this character it may be employed in the present investigation. Examination of our experimental results shows that, for them, the equation used by Lundén does not hold. With the equation of Arrhenius, however, satisfactory agreement can be obtained, in the case of ammonium chloride, throughout the available temperature range.

The Heat of Dissociation of NH_4Cl .—The heat of dissociation of ammonium chloride vapor has not been determined previously because the values of the dissociation constant at different temperatures are necessary for its calculation, and they have never been determined.

By combining Arrhenius' formula with the van't Hoff equation, there is obtained

$$d \ln K_c = - \frac{A_0}{RT^2} dt + \frac{C}{R} dT$$

and integration of this equation yields,

$$4.571 \frac{\log K_{c1} - \log K_{c2}}{T_1 - T_2} = - \frac{A_0}{T_1 T_2} + C. \quad (\text{IV})$$

¹ Arrhenius, "Energieverhältnisse bei Dampfbildung und bei elektrolytischer Dissoziation," *Meddel. från K. Vet. Akads. Nobelinstitut*, Band 2, No. 8.

From Equation IV the values of A_0 and of C may be found by solving the two simultaneous equations obtainable from the values of K_c at any three different temperatures; but we have used the following graphic method which is more general and more accurate. If Equation IV is written in the form,

$$y = -A_0x + C,$$

it is evident that it is the equation of a straight line. From each pair of values of K_c which is available from the data, and the corresponding temperatures, a value of both y and x may be obtained. If these values of y and x are plotted they will lie on a straight line, providing Equation IV represents the correct relation between U and T . The slope of this line will be A_0 , and its intercept on the y -axis will be C . From the fifteen possible pairs of the "average" values of K_c given in Table VI, we calculated fifteen values of x and y . These were then plotted, and the best

Fig. 5.—Calculation of the heat of dissociation of saturated ammonium chloride vapor. Plot of the equation, $y = -A_0x + C$.

representative straight line was drawn through them, as shown in Fig. 5. A_0 , the slope of this line, was found to be -12800 , and C , the intercept on the y -axis had the value 0.00967 , whence,

$$U = -12800 - 0.00967T^2 \text{ gram calories per mol.}$$

The fact that the results lie so well along a straight line shows that the van't Hoff equation, in conjunction with Arrhenius' relation between U and T , correctly represents the facts in the case of ammonium chloride. It is also to be noticed that the heat absorbed during dissociation increases as the temperature increases. This indicates that the molar heat of ammonium chloride vapor is less than the sum of the molar heats of its products of dissociation, and this conclusion is in accordance with the kinetic theory of gases.

Ammonium Bromide.

The Data.—The densities of saturated ammonium bromide vapor were determined between 300° and 388° , the range of temperature being determined by the same factors as in the case of ammonium chloride. Vapor density bulbs of type No. 2 (Fig. 1) were used, except at 300° and 388° . At these temperatures the "trap bulb," Fig. 1, No. 3, was employed. The ammonium bromide was recrystallized once from distilled water, then sublimed in a large evacuated glass tube, and finely pulverized.

The data of the individual vapor density determinations are presented in Table VII. For an explanation of this table see the discussion that

precedes Table II (ammonium chloride), which is identical in form. The accuracy of the ammonium bromide data is the same as in the case of the ammonium chloride, namely, about $\pm 2\%$.

In Table VIII are given the densities of saturated ammonium bromide vapor in the form in which they were used in the calculations. This table corresponds to Table III (ammonium chloride), and the explanation which precedes Table III applies also to it.

In order to facilitate the comparison of the observed vapor densities with the "completely dissociated" and the "undissociated" vapor densities, these have been plotted in Fig. 6.

Fig. 6.—Vapor densities of ammonium bromide: Curve I—Undissociated (calculated); Curve II—Observed; Curve III—Completely dissociated (calculated).

It will be seen that the observed vapor densities lie between the "completely dissociated" and the "undissociated" densities throughout the range of temperatures studied. This fact indicates that ammonium

bromide vapor is dissociated, although not completely. Furthermore, the measured vapor densities of ammonium bromide lie much nearer to the "undissociated" curve than do the measured densities of ammonium chloride (Fig. 2), so that ammonium bromide vapor is less dissociated than is ammonium chloride vapor.

The Degrees of Dissociation.--The degrees of dissociation of ammonium bromide vapor are calculated by the same method as were those of ammonium chloride. The results are presented in Table IX and are plotted in Fig. 3. The quantities in the several columns of Table IX have the same significance as those in the corresponding columns of Table IV (ammonium chloride).

TABLE IX.-- NH_4Br --DEGREES OF DISSOCIATION.

Temp. C.	Percentage dissociation.		Deviation of α from straight line.		% error in α . (Calcd.)
	Obsd.	Interpol.	Actual.	%.	
300°	16.1	47.9	—31.8
310°	..	43.6
320°	38.7	39.3	—0.6	1.5	4.3
330°	35.7	34.9	+0.8	2.3	9.8
340°	31.6	30.6	+1.0	3.3	7.1
350°	24.7	26.3	—1.6	6.1	6.5
360°	21.7	22.0	—0.3	1.4	5.4
370°	18.4	17.7	+0.7	4.0	3.7
380°	15.3	13.4	+1.9	14	18
388°	8.0	10.0	—2.0	20	12

Inspection of Table IX and of Fig. 3 will show that at 320° ammonium bromide vapor is about 39% dissociated and, as the temperature increases, the degree of dissociation *decreases* regularly until at 388° it is only about 8-10%. As was the case with ammonium chloride, a straight line represents the results within the experimental error of the observations.

As will be seen from Table IX, the deviations of the measured values of α from a straight line are, with one or two exceptions, less than the deviations calculated from the known experimental error in the observed vapor densities.

The exact degree of dissociation at temperatures below 320° is somewhat in doubt. If, below 320° , the degree of dissociation continued to vary linearly with the temperature, as it does above 320° , it should have a value of about 48% at 300° , with a corresponding vapor density of 0.000102 g. per cc. We first used bulbs of type No. 2 (Fig. 1), and obtained a set of nine densities with the average value $0.000135 \pm 3.1\%$ (not given in the table), corresponding to a dissociation of 11.1%. Later, we repeated the determination using the trap bulb, No. 3 (Fig. 1), and obtained the value cited above, namely 0.000130 g. per cc. (16.1% dissociation).¹ The mean of the two values 0.0001325, differs from each of the values by less than 2%. Since at this temperature the vapor pressure is very low, the total weight of the vapor filling the large bulb is only 8-10 mg. The agreement of the two sets within 4% is therefore better than one would expect under the conditions. On the other hand, it seems improbable that the real value was 0.000102, and that the errors in the two sets were as great as 25% and 30%, respectively. Speaking conservatively, all that can be said is, that the measurements indicate that the degree of dissociation of ammonium bromide vapor passes through a maximum near 320° , but that this inference depends entirely upon the vapor density at 300° , which is the one most subject to error in the series.

As already pointed out, the measurements are not made at constant pressure, but at pressures which rise rapidly with rising temperature. Thus between 330° and 380° the total pressure of all components increases from 134.7 mm. to 644.4 mm., while the partial pressure of free ammonia (or HBr, see Table XV) increases from 34.6 mm. to 57.8 mm. only. Calculation shows that if the total pressure were to be kept constant at 134.7 mm. then the partial pressure of ammonia would change from 34.6 mm. to 23.5 mm. Hence, the degree of dissociation would decrease from 35% to 21% only. Thus the decrease shown in Table IX is greatly exaggerated by the effect of increasing total pressure. Ammonium bromide vapor is apparently the only dissociating gas whose degree of dissociation at constant pressure is known to decrease with increasing temperature.

In this connection attention should be called to the fact that this behavior is not unique, in the sense that many, and therefore possibly all

¹ This case illustrates very strikingly the way in which a moderate error in the observed density gives rise to a very large error in the degree of dissociation calculated therefrom. Here the higher of the two values obtained for the density exceeded the lower by 4%, while one of the corresponding, calculated values of α is no less than 45% greater than the other (see p. 49).

other substances are *known* to show the opposite behavior. If this were true, the isolated nature of the phenomenon would enjoin extreme caution before acceptance. The situation is, rather, that we lack information in regard to almost all the other dissociating substances, and do not know what their behavior in this respect is. For example, the vapor density of ammonium bromide was previously investigated by Deville and Troost by the Dumas method, and the results did give a slightly greater (2%) density (and therefore less dissociation) at the higher temperature (Table I). But this difference was quite naturally attributed to error, due to the inadequacy of the method when applied to such substances. The data thus far obtained in regard to the vapor densities of solids dissociating at high temperatures simply have not usually been such as would enable us to distinguish with certainty between cases in which, with rising temperature, the dissociation increased, and those in which it decreased.

The Latent Heat of Vaporization.—The only previous attempt to determine the molar latent heat of vaporization of ammonium bromide is that of F. M. G. Johnson,¹ who, by using the equation $d \ln P/dT = Q/2RT^2$, in conjunction with his measurements of the vapor pressures of ammonium bromide, found the value 45.4 kg. cal. at 297–394°. Since this equation involves the assumption that ammonium bromide vapor is completely dissociated, Johnson's value is larger than the correct value, and does not represent the heat absorbed when one mol of ammonium bromide vaporizes in equilibrium with its saturated vapor.

We have calculated the molar latent heat of vaporization from the following equation, which was derived and explained when the latent heat of vaporization of ammonium chloride was discussed, namely,

$$L = T \frac{P}{760} \left[\frac{A}{0.4343 T^2} + \frac{B}{T} \right] \frac{0.02419}{\Delta_{mi}} \text{ kg. cal.}$$

For ammonium bromide, $A = 2057$, and $B = 9.540$.²

The values of the latent heat of vaporization thus obtained are given in Table X.

TABLE X.—NH₄Br—LATENT HEATS OF VAPORIZATION (Kg. cal. per mol).

300°	320°	330°	340°	350°	360°	370°	380°	388°
23.5	28.7	28.1	27.4	26.8	26.1	25.4	24.7	24.1

These values of the latent heat of vaporization are less than those of Johnson, as would be expected from the nature of the error in his determinations. The fact that above 320° the latent heat of vaporization decreases is not unusual. If the vapor of a solid or a liquid does not dissociate, the latent heat of vaporization will, in general, decrease with increasing temperature, because the specific heat of the solid or liquid is greater than that of its

¹ F. M. G. Johnson, *Z. physik. Chem.*, 65, 38 (1908–9).

² Smith and Calvert, *THIS JOURNAL*, 36, 1368 (1914).

saturated vapor. Ammonium bromide, therefore, behaves in this respect exactly like a normal, nondissociated substance. It must consequently be concluded that the disturbing influences upon the heat of vaporization (*e. g.*, the heat involved in the dissociation of the vapor) are insufficient to affect the general run of the results, or are approximately constant throughout the temperature range considered.

The Dissociation Constants and the Heat of Dissociation.—The dissociation constants of ammonium bromide vapor were calculated from the data in Table VIII by the same relation which was used in the case of ammonium chloride, namely,

$$K_c = \frac{\alpha^2}{1 - \alpha} \Delta_{mi}.$$

As under ammonium chloride, two series of values of K_c were determined, one by using the observed values of α and the second by using the "interpolated" values of α . The latter series represents the best average of the measured dissociation constants. These observed and "average"

Fig. 7.—Dissociation constants of saturated ammonium bromide vapor.

dissociation constants are given in Table XI; and they are plotted in Fig. 7. The "average" values are represented by the curve, and the observed values by the points which lie on either side of the curve.

TABLE XI.— NH_4Br —DISSOCIATION CONSTANT, K_c .

Temp.	Observed.	Average.	Temp.	Observed.	Average.
300°	0.03409	0.03458	350°	0.03396	0.03453
310°	0.03481	0.03481	360°	0.03390	0.03400
320°	0.03478	0.03497	370°	0.03353	0.03327
330°	0.03525	0.03497	380°	0.03311	0.03236
340°	0.03517	0.03483	388°	0.03198	0.03158

It will be seen that the dissociation constant first increases to a maximum at 320°, and then decreases. If we consider first the decrease, we see that this has an important bearing upon the heat of dissociation. If

in the van't Hoff equation, $d \ln K_c/dT = -U/RT^2$, the term $d \ln K_c/dT$ is negative, as it is here above 320° , then U must be *positive*. That is to say, above 320° , heat will be *evolved* by the reaction. Hence, the data show that above 320° the dissociation of ammonium bromide vapor is accompanied by evolution of heat. This result was wholly unexpected. If the decrease had been slight, it might have been explained as due to errors of observations, or to inadequacy of the method, for the measurement of vapor densities at high temperatures is undoubtedly difficult and subject to considerable errors. The decrease is so very rapid, however, the values at the various temperatures are so regular in their decrease, and the estimated errors of observation are relatively so small (see Table VII), that no doubt can exist that the decrease really occurs.

As regards the maximum point, the phenomena are the opposite of those shown by hydrogen iodide, where at low temperatures heat is given out in the dissociation and at higher temperatures is absorbed, so that the dissociation constant passes through a minimum. The cases are not parallel, however, because the decomposition of the hydrogen iodide is accompanied by recombination to form H_2 and I_2 , and the case is not one of simple dissociation like that of ammonium bromide. Although the case of ammonium bromide is thus unique among gases, there are analogies among liquids which, to a certain extent, reconcile us to its occurrence. Thus, Lundén¹ has found that with rising temperature the ionic dissociation constants of ammonium hydroxide and of acetic acid pass through maxima. However, the case is not strictly analogous, because the conditions in a system involving two components, such as a solution, are different from those in a system involving only one component like the present one. The analogy is closer in a single ionizing liquid like water. According to Arrhenius' equation $U = A_0 - CT^2$, U being here the heat of ionic dissociation, there must be for each substance some temperature at which the dissociation reaches a maximum. This happens when $U = 0$, and therefore $T = \sqrt{A_0/C}$. In the case of water this temperature happens to fall within the experimental range. According to A. A. Noyes² $U = \text{zero}$ for water between 250° and 275° . According to Arrhenius³ $U = \text{zero}$ for water at 229° . It is therefore quite conceivable that similar relations should exist in dissociating vapors.

An attempt to obtain an expression for the values of the heat of dissociation of ammonium bromide by means of the combined van't Hoff and Arrhenius equations, which served so well in the case of ammonium chloride, was made. It was found, however, that for ammonium bromide this equation does not represent the relation between the dissociation

¹ Lundén, *J. chim. phys.*, **5**, 598 (1907).

² Carnegie Inst. of Washington, Publication No. 63, 233 (1907).

³ "Theories of Solutions" 1912, p. 212.

constants and the heat of dissociation. Arrhenius himself found that his interpolation formula does not always apply where a change in the sign of U occurs. In such cases it can be used with success only where the sign of U passes through zero at a moderate temperature. For example, it does not represent the heat of electrolytic dissociation of water at temperatures much above the boiling point of water, unless powers of T higher than the second are included. Since, in the present instance, the change in sign occurs as high as 320° , the Arrhenius formula could not be expected to hold.

Ammonium Iodide.

The Data.—The densities of saturated ammonium iodide vapor were determined from 300° to 380° by using the "trap" bulb, Fig. 1, No. 3. The bulbs remained in the nitrate bath for thirty minutes each. Ammonium iodide, once recrystallized, and dried at 100° *in vacuo*, was used. The vapor density data are presented in Table XII.

The error in the ammonium iodide vapor densities is, at several of the temperatures, greater than that observed for the chloride and bromide; and the average values of the vapor densities do not lie so smoothly on a curve. This greater irregularity may be due to the slow decomposition of the hydrogen iodide,¹ although no iodine vapor was ever noticed in the hot vapor density bulbs immediately after they were removed from the nitrate bath (see also p. 67).

The vapor density results are summarized in Table XIII, as was done in Table III for ammonium chloride. The dissociation pressures given

¹ Smith and Calvert, *THIS JOURNAL*, 36, 1370 (1914).

in this table are those of Smith and Calvert.¹ The "interpolated" values of the vapor density given in Table XIII were not determined by calculation from the interpolated values of α , as in the case of ammonium chloride, because, as will be seen below, the values of α for ammonium iodide cannot be determined. The "interpolated" values were therefore found by graphical interpolation from the best representative curve which could be drawn through the observed vapor densities. This curve, together with the "undissociated" and "completely dissociated" vapor density curves are given in Fig. 8.

Fig. 8.—Vapor densities of ammonium iodide: Curve I—Undissociated (calculated); Curve II—Observed; Curve III—Completely dissociated (calculated).

Discussion of Results.—Inspection of Table XIII and of Fig. 8 shows several interesting facts concerning ammonium iodide vapor. It will be noticed that, below 340–350°, the observed densities of the saturated vapor are larger than the densities calculated for no dissociation. This means that ammonium iodide vapor is associated. However, it does not exclude the possibility that part of the vapor is also dissociated at the same time, although it does indicate that the amount of association at lower temperatures is relatively larger than the amount of dissociation. The

¹ Smith and Calvert, *Loc. cit.*, 1371.

equilibrium in the vapor at any temperature may be represented most simply by the equation,

It will be seen also that, as the temperature increases, the observed vapor densities become first equal to, and then less than the "undissociated" vapor densities. This indicates that the amount of association decreases and the amount of dissociation increases as the temperature of the vapor rises.

The unexpected character of the results suggests the possibility of some secondary reaction. Thus, if the hydrogen iodide itself dissociated, the free iodine might interact with the ammonia to produce free nitrogen and hydrogen iodide. This reaction would result in a diminished partial pressure of ammonia, which in turn would permit further vaporization of the salt, and so give greater apparent densities. A similar reaction might even be imagined to have occurred in the case of the bromide. Such a reaction, however, would have left permanent gases (nitrogen and hydrogen) in the bulb. Now, in all the measurements in this paper, the evacuated bulbs, when opened under water, were filled completely by the liquid. The minute bubble of gas (much less than 1 cc.) which was visible, appeared to come mainly from the atmospheric gases dissolved in the water. Hence no reaction producing a permanent gas can have occurred.

The association of ammonium iodide vapor renders it impossible to make for it many of the calculations which were made for ammonium chloride and bromide. If it is assumed that the equilibrium in the vapor is represented by Equation I above, and if α is the percentage of the total number of NH_4I molecules dissociated, and β the percentage associated at any temperature, then

$$(\alpha - 0.5 \beta) = \frac{\delta_m - \Delta_m}{\Delta_m}. \quad (\text{II})$$

This is the only relation between α and β which can be obtained from our data, and therefore, since there is only one equation involving these two unknown quantities, it is impossible to determine either of them. Since α and β are indeterminable, the dissociation constants, the heat of dissociation, and the partial pressures cannot be calculated, because the values of α and β are necessary for the calculation of each of these.

Although it is thus impossible to determine the actual degree of association or of dissociation of the vapor, the maximum and minimum values at any temperature may be estimated. At temperatures below that at which the observed and the "undissociated" vapor density curves cross each other, the minimum value of β may be found by placing α in Equation II equal to zero, and solving for β . The minimum value of α in this temperature region is, of course, zero. At temperatures above the inter-

section of these two curves, the minimum value of β is zero, and the minimum value of α may be found by assuming β in Equation II to be zero, and solving for α . The maximum values of α and β may be determined by assuming that all of the NH_4I molecules in the vapor have associated and dissociated; *i. e.*, by assuming that $\alpha + \beta = 1.00$, and then solving the simultaneous equations

$$\begin{aligned}\alpha - 0.5\beta &= \frac{\delta_m - \Delta_m}{\Delta_m} \\ \alpha + \beta &= 1.00\end{aligned}$$

In this way we have estimated that ammonium iodide vapor at 300° is between 24% and 83% associated, and from 0% to 17% dissociated. At 380° , it is between 0% and 59% associated, and from 11% to 41% dissociated. These estimates are, of course, based upon the assumption that there are no ammonium iodide molecules in the vapor more complex than the type $(\text{NH}_4\text{I})_2$, but they give some idea as to the conditions possibly present.

The Latent Heat of Vaporization.—F. M. G. Johnson¹ has found the value 44.5 kg. cal. for the molar latent heat of vaporization of ammonium iodide by the same method which he used for the chloride and bromide. But this method involves the assumption of the complete dissociation of the vapor, and so his result is too large. This is apparently the only estimate of the latent heat of vaporization of ammonium iodide which has thus far been made.

We have computed the molar latent heat of vaporization from the data in Table XIII, by the method we used for ammonium chloride and bromide, the equation for ammonium iodide being

$$L = T \frac{P}{760} \left[\frac{7715}{0.4343 T^2} - \frac{10.04}{T} \right] \frac{0.02419}{\Delta_{mi}} \text{ kg. cal.}$$

The values obtained are given in Table XIV. Those at 310° and 330° are in italics because they were calculated from purely interpolated data, there being no measured vapor densities of ammonium iodide at these temperatures. In the last line of the table are given the differences between the successive values of the heat of vaporization, in order that its mode of variation with the temperature may be clearly seen.

TABLE XIV.— NH_4I —LATENT HEATS OF VAPORIZATION (Kg. cal. per mol).

300°	310°	320°	330°	340°	350°	360°	370°	380°
18.0	19.0	20.4	21.7	22.8	23.2	23.6	23.9	24.8
	1.0	1.4	1.3	1.1	0.4	0.3	0.3	0.9

The latent heat of vaporization of ammonium iodide increases as the temperature increases. Since the latent heat of vaporization of substances whose vapors are neither associated or dissociated generally

¹ F. M. G. Johnson, *Z. physik. Chem.*, **65**, 40 (1908-9).

decreases with a rise of temperature, the above fact makes it probable that heat is absorbed during the dissociation of ammonium iodide vapor, and that the amount of heat absorbed by dissociation increases as the temperature increases. This latter fact would be expected, because it has already been shown that the amount of dissociation of ammonium iodide vapor increases as the temperature rises.

The Partial Pressures of the Ammonium Halides.—The partial pressures for ammonium iodide could not be calculated on account of the association of its vapor. Taking ammonium chloride as an example, and assuming the equilibrium in the vapor to be of the type,

the partial pressures of the three gases in the vapor are given by the formulae

$$p_{\text{NH}_4\text{Cl}} = P_{\text{Total}} \frac{2\Delta_{mi} - \delta_m}{\delta_m}, \text{ and } p_{\text{NH}_3} = p_{\text{HCl}} = \frac{P_{\text{Total}} - p_{\text{NH}_4\text{Cl}}}{2}.$$

P_{Total} is the dissociation pressure of the ammonium halide in question. The data for ammonium chloride and bromide, given in Tables III and VIII, respectively, were used for calculating the partial pressures, and the results are presented in Table XV.¹

Summary.

Measurements of the densities of the saturated vapors of ammonium chloride (280° to 330°), bromide (300° to 388°), and iodide (300 to 380°) are recorded. With these data, and the previously measured dissociation pressures, a study is made of the degrees of dissociation, dissociation constants, heats of dissociation, latent heats of vaporization, and partial pressures of these substances, with the following results:

¹ In order to facilitate reference and comparison, we have also given in Table XV the dissociation pressures of ammonium chloride and bromide as measured by Smith and Calvert (*Loc. cit.*).

Ammonium chloride vapor is 67-63% dissociated between 280° and 330°; and although the degree of dissociation is very nearly constant, it decreases slightly between these temperatures. Ammonium bromide vapor is about 39% dissociated at 320°, and above this temperature the percentage dissociation decreases linearly, until, at 388°, it is about 10%. Ammonium iodide vapor is associated, especially at lower temperatures, but the amount of association decreases, and the dissociation increases as the temperature rises. The assumption that the vapors of the ammonium halides are completely dissociated is therefore no longer tenable.

The dissociation constants of ammonium chloride and bromide are calculated. That of ammonium chloride vapor increases steadily with the temperature, whereas that of ammonium bromide vapor passes through a maximum near 320°, and then decreases.

The heat of dissociation of ammonium chloride vapor is computed by the van't Hoff equation, and is represented by the relation, $U = -12800 - 0.00967T^2$ gram calories (U is heat evolved). The mode of variation of the dissociation constant with the temperature indicates that the dissociation of ammonium bromide vapor above 320° is accompanied by the evolution of heat, but the actual value of the heat of dissociation can not be computed.

The latent heats of vaporization are calculated by the Clausius-Clapeyron equation. That of ammonium chloride is 32.9 kg. cal. between 280° and 330°, and is constant within 1%; that of ammonium bromide is 28.7 kg. cal. at 320°, and decreases to 24.1 at 388°; that of ammonium iodide increases from 18.0 kg. cal., at 300°, to 24.2 at 380°.

The partial pressures of the various components in the ammonium chloride and bromide vapors are computed.

NICHOLS LABORATORIES OF INORGANIC CHEMISTRY,
COLUMBIA UNIVERSITY, NEW YORK, N. Y.

ON THE RATE OF REDUCTION OF MERCURIC CHLORIDE BY SODIUM FORMATE.

By G. A. LINHART.

Received November 12, 1914.

In a previous paper¹ an investigation of the rate of the reduction of mercuric chloride by phosphorous acid was described. The purpose of this article is to present the results of a similar study of the rate of reduction of mercuric chloride by sodium formate, with special reference to the influence of sodium chloride upon it, which has already been shown to have a great effect on the reduction by phosphorous acid.

Very recently, after the experimental work described below had been

¹ Linhart, *Am. J. Sci.*, **35**, 353-368 (1913).

completed, a preliminary communication on this same subject was published by Findlay and Davies.¹ These investigators conclude from a large number of experiments at various temperatures and concentrations that the reaction between sodium formate and mercuric chloride is one of the second order, because when their experimental results are substituted in an equation representing a reaction of the third order the reaction velocity coefficient gradually increases to about 40%, while if substituted in one representing a reaction of the second order, the velocity coefficient decreases only by about 17%. As these figures created some doubt, in the authors' own minds as to the mechanism of this reaction, they cited the similar reaction between mercuric chloride and phosphorous acid,² which has been shown to be of the second order, and state that a similar explanation to justify the assumption that the reaction between mercuric chloride and sodium formate is theoretically one of the second order, appears to be very doubtful. It will be evident from what follows, not only that the mechanism of the reaction between mercuric chloride and sodium formate may be interpreted in a similar manner to that of mercuric chloride and phosphorous acid, but that concordant velocity constants may be obtained if the experiments are performed under the proper conditions.

There are two opposing factors which tend to obscure the mechanism of the reaction between mercuric chloride and sodium formate. First, the association of the mercuric chloride in water solution;³ and secondly, the formation of sodium chloride. The double molecules of mercuric chloride being present in considerable proportion at higher temperatures and gradually dissociating with the dilution would tend to accelerate the velocity of the reaction to some extent, as the simple molecules are found to be more reactive. On the other hand, the sodium chloride, increasing in concentration as the reaction proceeds, combines with the mercuric chloride, forming NaHgCl_3 , and subsequently Na_2HgCl_4 , which react with the sodium formate extremely slowly, as is shown in the table, Expt. 7. Since the second factor very much more than compensates the first, the velocity coefficient, K , will consequently decrease. In order to overcome these difficulties the reaction must be allowed to take place either at such dilutions that the mercuric chloride is practically all in the form of simple molecules, HgCl_2 , so that the resulting sodium chloride can exert no appreciable influence; or, in a large excess of sodium chloride so that there could be no free HgCl_2 molecules, and the influence of the small amount of sodium chloride, formed in the course of the reaction, would

be negligible as compared with the total amount initially present. There is another factor which tends to modify the course of the reaction, namely, the formation of hydrochloric acid, but this may easily be remedied either by the addition to the reaction mixture of a soluble salt of a weak acid, as was recommended in a previous paper,¹ or by the addition of a sufficient amount of finely divided barium carbonate.

Experimental.

Standardization of the Mercuric Chloride and Sodium Formate.—A weighed amount of mercuric chloride was dissolved in distilled water or in aqueous sodium chloride of known concentration. Of this solution 10 cc. were pipeted off, by means of a carefully calibrated pipet, and transferred into several glass test tubes, of about 40 cc. capacity, which had previously been constricted at about $1\frac{1}{2}$ " from the mouth to a size just large enough to admit the stem of the pipet and to allow the displaced air to escape. To this were added 10 cc. of a solution containing about twice the theoretical amount of sodium formate. The tubes were then sealed, allowed to cool, the contents well mixed, and the tubes submerged in a thermostat kept at 40° . When two consecutive analyses of the mercurous chloride in the tubes about twenty-four hours apart showed no increase in the amount of the mercurous chloride, the reduction was considered complete. Moreover, these results always agreed within 0.2–0.3%, with the theoretical amount of mercurous chloride calculated from the mercuric chloride originally present. In a similar manner the concentration of the sodium formate was determined by using an excess of mercuric chloride.

Reaction Velocity Measurements.—All experiments were carried out in sealed glass test tubes. As soon as two tubes were filled with 10 cc. of the standardized mercuric chloride containing the sodium chloride, and 10 cc. of the standardized sodium formate, containing the sodium acetate, they were sealed, allowed to cool, shaken and submerged in a thermostat kept at 40° , where they were held in position by means of coiled brass springs. The time, t , was counted from the moment the tube was submerged until it was removed from the thermostat and plunged into ice water to check the reaction. At definite intervals a tube was withdrawn; the capillary tip carefully broken off and three scratches made with a sharp triangular file in a horizontal plane, on each side of which was placed a folded piece of wet filter paper. The tube was then brought in a vertical position at the point of a small blast lamp flame, care being taken not to allow the upper part of the tube to fly off, as it often contained some

¹ Linhart, *New York Med. J.*, June 14, 1913. The addition of sodium acetate, sodium citrate, and sodium bicarbonate, in particular, causes the reaction between mercuric chloride and phosphorous acid to become instantaneous, while in the case of mercuric chloride and sodium formate the action is merely accelerated.

mercurous chloride. After the tube was thus cracked the upper part was lifted off and the contents filtered through an ignited and weighed perforated platinum crucible, fitted with an asbestos mat. The precipitate was washed first with warm water, then with a little dilute hydrochloric acid, and finally with warm water until the wash water was free of impurities. It was found advisable in filtering the mercurous chloride to use light suction at first to avoid clogging of the asbestos mat, which would vitiate the experiment because of the delay in stopping the reaction. After most of the moisture had been exhausted by the aspirator, the crucible was suspended in a drying oven maintained at a temperature between 105° and 110° for thirty minutes. The crucible was then allowed to cool in a desiccator and weighed.

Discussion of the Results.

It is evident from Expts. 1, 2 and 7 that fairly concordant velocity constants may be obtained if the reaction proceeds under favorable conditions. It is also interesting to note that as the initial concentration of the sodium chloride is increased from 0.0 in Expt. 3 to twice normal in Expt. 7, the velocity coefficient gradually approaches constancy until in Expt. 6 the difference between the first and the last figures is only about 6%; also the total effect of the sodium chloride in the lowering of the magnitude of the velocity coefficient is seen to vary gradually from approximately 1.8 in Expt. 1 to 0.105 in Expt. 7. As far as the constants of Expts. 1, 2, 6 and 7 show, then, the reaction between mercuric chloride and sodium formate is evidently one of the second order, and it only remains to make the theory fit the figures.

The reaction between mercuric chloride and sodium formate may be represented in a similar manner to the one between mercuric chloride and phosphorous acid, thus:

where reaction (b) is assumed to be practically instantaneous. Similarly:

In (a) we have a well-known compound formed, hypophosphoric acid, readily hydrated and incapable of reducing mercuric chloride except indirectly as indicated in (b). But no such compound as $-\text{COONa}$ is known. However, two such radicals in their nascent state might unite to form one molecule of sodium oxalate. But it is well known that sodium oxalate does not have the property of reducing mercuric chloride under ordinary conditions. Moreover, no trace of oxalates could be detected at any stage of the reaction. The most plausible assumption, then, is that the secondary reaction is similar to (b); that is, two radicals at the instant of liberation combine with one molecule of water to form one molecule of sodium formate and one of sodium hydrogen carbonate which is at once decomposed by the hydrochloric acid generated at the same time. The reactions, although occurring simultaneously, may be represented by the following equations:

Denoting the molal concentration of the mercuric chloride by A, that of the sodium formate by B, and by x the amount of the reacting substances decomposed, or the amount of mercurous chloride formed at time t , we have

$$\frac{dx}{dt} = K(A - X)(B - X + \frac{1}{2}X)^1$$

$$\frac{dx}{dt} = \frac{1}{2}K(A - X)(2B - X)$$

$$K = \frac{(2)(2.3)}{(2B - A)t} \log \frac{A(2B - X)}{2B(A - X)}$$

Summary and Conclusion.

1. It has been shown fairly conclusively, both experimentally and theoretically, that the reaction between mercuric chloride and sodium formate, like that between mercuric chloride and phosphorous acid, is one of the second order.

2. The retarding influence of the sodium chloride formed in the reaction is remarkable. Its effect, however, was reduced to a minimum by working, on the one hand, with dilute solutions of mercuric chloride, and, on the

¹ Since for every two molecules decomposed one molecule is regenerated, see also *Am. J. Sci.*, 35, 353-368 (1913).

other hand, by adding a large excess of sodium chloride initially to the reaction mixture, so that the amount of sodium chloride formed in the reaction was rendered negligible. Under these conditions concordant velocity constants were obtained as may be seen from Expts. 1, 2 and 7.

The experimental part of this work was begun at the Kent Chemical Laboratory of Yale University.

THE EFFECT UPON THEIR SOLUTION TENSIONS OF DISSOLVING THE ALKALI AND ALKALI EARTH METALS IN MERCURY, AND THE CONSTITUTION OF SUCH SOLUTIONS.

By GEORGE MCPHAIL SMITH.

Received November 2, 1914.

In a discussion of the constitution of liquid amalgams, C. H. Desch¹ makes the following statements: "In simple eutectiferous series, in which the freezing-point curve shows no indication of the formation of compounds, we may safely accept the conclusion arrived at by the three methods described above (*i. e.*, the cryoscopic, vapor-pressure, and electromotive-force methods), that the dissolved metals are monatomic. *In series in which compounds occur, it remains as yet an open question whether the same condition prevails, or whether compounds containing a single atom of the dissolved metal in each molecule, are also present.*"² The only experimental method which gives any indication of a definite answer to this question is that of measuring the velocity of diffusion in liquid metals." He then proceeds to describe a portion of a paper by the writer³ in which this method is developed by the latter by means of M. von Wogau's⁴ experimental measurements of the rate of diffusion of various metals in mercury, and in which it is shown by this method that, in the case of the alkali and alkali earth amalgams, such compounds do actually exist in the mercurial solutions.⁵

In the above-mentioned paper,³ however, another experimental method is also developed, which, although it is at least capable of furnishing confirmatory evidence of the same thing, was in that paper apparently not explained sufficiently in detail. It is with the purpose of furnishing a clearer exposition of the latter method that the present paper is written.

⁴ Max von Wogau, *Ann. Physik*, **23**, 345 (1907).

⁵ The diffusion method as applied to the study of the constitution of metallic solutions has subsequently been placed upon a firm theoretical basis (cf. G. Mc. P. Smith, *THIS JOURNAL*, **36**, 859 (1914)).

When a metal is immersed in a salt solution (in which, if present at all, its ions are limited in concentration), the solution tension of the metal tends to drive some of its ions into the solution, whereat the latter becomes positively charged, and the metal negatively charged. These charges give rise to a force component, which on the one hand tends to prevent the entrance of more positive ions into the solution, and on the other hand seeks to drive the positive ions in the solution back to the metal. One of two things must now take place. Either the solution tension of the metal is exactly compensated by the electrostatic charges, in which case there results an equilibrium; or, as a result of the magnitude of the solution tension, the electrostatic charge attains so high a value, that other positive ions which are contained in the solution are forced out of it and deposited on the metal.

In general, when a metal is immersed in a salt solution of another metal (which may or may not contain its own ions), the ions of the second metal will separate the more readily, the higher their own concentration, the greater the solution tension of the first metal, and the lower the ionic concentration of the first metal. If we designate the electromotive force necessary for the electrolytic separation of the first metal by ϵ , we have,

$$\epsilon = \frac{RT}{n} \ln \frac{P}{p},$$

(in which R is the gas constant, T the absolute temperature, P the electrolytic solution tension of the metal, p the osmotic pressure of its ions, and n the valency of its ions), and the separation of the second metal must take place as soon as the osmotic pressure of its ions and the electrostatic pull are able to overcome the electrolytic solution tension of the second metal, *i. e.*, the relation,

$$\epsilon_1 > \epsilon_2, \text{ or } \sqrt[n_1]{\frac{P_1}{p_1}} > \sqrt[n_2]{\frac{P_2}{p_2}},$$

must hold, in which the index 1 refers to the first metal, 2 to the second metal, and n_1 and n_2 are the valencies of the two metals.

The electromotive series of the univalent alkali metals reads:

Disregarding their action upon water, we should expect each metal in the series, beginning at the positive end, to be capable of displacing from aqueous salt solutions any metal which follows it in the series, and, under like conditions, this displacement should take place the more readily, the farther apart the two metals stand in the series. In other words, we should expect, under ordinary conditions, to have the relation

$$\frac{P_+}{p_+} > \frac{P_-}{p_-},$$

and the more electropositive metal should displace the more electro-negative one from its salt solutions.

Now, the relative magnitudes of the above two expressions, on which depends the direction of the displacement, can be affected in two ways, with the possibility of reversing them altogether. First, the values of p_+ and p_- can be changed at will, by regulating the ionic concentrations, and, second, the values of P_+ and P_- can be altered by substituting metallic solutions, or compounds, of the metals, in place of the metals themselves.

To take a concrete example, it appears very probable that finely divided sodium and potassium might be found capable of readily displacing one another from concentrated aqueous salt solutions, were it not for the action of the metals upon the aqueous solvent. On providing, however, for very much lower solution tensions of the metals—by the substitution of liquid amalgams for the free metals—their action upon the water is almost entirely prevented, and the reversible displacement of sodium and potassium from their aqueous salt solutions can be realized without difficulty.

In the experiments to be detailed in this paper, each amalgam of the respective pairs, Na and K, Na and Rb, and Na and Cs, in dilute equimolar mercurial solution, was allowed to act at 24° upon the corresponding one of three equivalent aqueous solutions, containing equimolar quantities of NaCl and KCl, of NaCl and RbCl, and of NaCl and CsCl, respectively; and, as will be seen from the data in Table I, equilibria were attained in all cases.¹

TABLE I.—EQUILIBRIUM DATA AT 24° .²

No.	Amalgam.	Total normal concentration of salt solution.	Quantity of solution taken. Cc.	Quantity of amalgam taken. G.	Equiv. fractions of salts present in the solution.		Atomic fract. of the alkali metals in the amalgam.		Equilibrium constant $\frac{(\text{MeHg}_x)(\text{NaCl})}{(\text{NaHg}_x)(\text{MeCl})}$	Mean value.
					(NaCl).	(MeCl).	(MeHg ₂)	(NaHg ₂)		
1a	0.167% Na	4.000	50.0	50	0.50	0.50	0.2290	0.7710	0.297	0.31
1b	0.28% K	4.000	50.0	50	0.50	0.50	0.2461	0.7539	0.326	
2a	0.167% Na	4.000	25.0	57	0.50	0.50	0.2635	0.7364	0.358	
2b	0.62% Rb	4.000	25.0	50	0.50	0.50	0.2739	0.7260	0.377	0.37
3a	0.167% Na	4.000	25.0	25	0.50	0.50	0.3244	0.6755	0.480	
3b	0.98% Cs	4.000	25.0	25	0.50	0.50	0.3295	0.6705	0.491	0.49

Now, at equilibrium, we have in the cases of these univalent metals the relationships, $P_{\text{Na}}/p_{\text{Na}} = P_{\text{Me}}/p_{\text{Me}}$; and, since $p_{\text{Na}} = p_{\text{Me}}$ in each

¹ Full details of these experiments have been published elsewhere by the writer (cf. *Z. anorg. Chem.*, 58, 381 (1908); *Z. physik. Chem.*, 73, 424 (1910)).

² The general formula MeHg_x is in this table used to represent either hydrargyride molecules (each containing only one atom of the amalgamated metal), or simply monatomic molecules of Me. In the latter case $x = 0$.

of the equimolal mixed-salt solutions employed in these experiments,¹ it follows that, in each amalgam at equilibrium, $P_{Na} = P_{Me}$. If, now, we are justified in the conclusion that, in dilute mercurial solution, the solution tension of a given alkali metal is roughly proportional to its concentration in the metallic solution,² then we are in a position to calculate the relative magnitudes of the solution tensions of these four metals in their dilute equimolal mercurial solutions. We have, at 24°, the relationships:³

$$P_{(Cs)} = \frac{0.6730}{0.3270} P_{(Na)}; P_{(Rb)} = \frac{0.7312}{0.2688} P_{(Na)}; P_{(K)} = \frac{0.7625}{0.2375} P_{(Na)};$$

$$i. e., P_{(Na)} : P_{(Cs)} : P_{(Rb)} : P_{(K)} = 1.00 : 2.06 : 2.72 : 3.21$$

It is thus seen that the solution-tension magnitudes of the free metals—which decrease in the order, Cs, Rb, K, Na—are, in the case of the first three metals, reversed upon dissolving the metals in an excess of mercury; they then decrease in the order K, Rb, Cs, Na. The same is true of the alkali earth metals: while the solution tensions of the free metals decrease in the order Ba, Sr, Ca, those of the metals in equimolal liquid mercurial solution decrease in the order Ca, Sr, Ba. It may be added that lithium, the least electropositive of the free alkali metals, becomes, in mercurial solution, the most electropositive of them all.⁴

Taken in connection with the contents of our introductory paragraph, these facts are regarded by the writer as furnishing very good evidence that dilute mercurial solutions of the alkali and alkali earth metals are solutions of mercury compounds of the respective metals. It has been shown by Ramsay,⁵ Heycock and Neville,⁶ G. Meyer,⁷ and others, that dilute mercurial solutions of metals are governed by the same laws with respect to the depression of the vapor pressure, the freezing point, etc., of the solvent, as are ordinary dilute solutions. Therefore, upon dissolving small, equimolal quantities of the alkali or alkali earth metals in equal, large quantities of mercury, if, as has often been assumed,⁸ they exist in solution in the form

¹ Cf. G. McP. Smith, *THIS JOURNAL*, 32, 502 (1910); 35, 39 (1913).

² Cf. G. Meyer, *Z. physik. Chem.*, 7, 447 (1891); T. W. Richards and R. N. Garrod-Thomas, *Ibid.*, 72, 165 (1910). It would, however, be more exact to consider the solution tension of the alkali metal as proportional to the concentration of $MeHg_x$ in the dilute solution; but in the case of very dilute amalgams both considerations lead to results that are practically identical (cf. F. Haber, *Z. physik. Chem.*, 41, 399 (1902)).

³ The symbols $P_{(Na)}$, etc., are used to indicate the relative solution-tension magnitudes of the metals in dilute equimolal mercurial solutions, such as those listed in the first column of Table I.

⁴ Concerning the behavior of the alkali earth metals and of lithium, Cf. G. McP. Smith, *Am. Chem. J.*, 37, 507 (1907); *Z. anorg. Chem.*, 58, 381 (1908).

⁵ *J. Chem. Soc.*, 55, 521 (1889).

⁶ *Ibid.*, 55, 666 (1889); 57, 376 (1890).

⁷ *Z. physik. Chem.*, 7, 447 (1891).

⁸ G. Meyer, *Ibid.*, 7, 447 (1891); M. von Wogau, *Ann. Physik*, 23, 345 (1907).

of free monatomic molecules, then we should expect their solution tensions to be indeed lowered, but in a more or less uniform manner; the relative magnitudes of their solution tensions should not be greatly altered. If, however, they enter into combination with mercury to form compounds containing only one atom of the amalgamated metal to the molecule, and if it is these compounds which are present in solution in the excess of mercury, then we should expect the solution tensions of the metals to be lowered to a very much greater degree, and *not* uniformly, but differently, depending upon the relative affinities of the metals for mercury.¹ The latter is what actually does happen; and, moreover, it would be difficult to explain the analogous behavior in this respect of the metals K, Rb, and Cs, on the one hand, and of Ca, Sr, and Ba, on the other—the members of two neighboring triads in the periodic system—on any other basis than that of the existence in mercurial solution of the corresponding members of the two triads in the form of analogously constituted compounds. Furthermore, it is well known that alkali metals are capable of entering into combination with mercury, even at ordinary temperatures, with the formation of crystalline compounds; and, *in the light of the mass law, it would indeed be a remarkable fact if such compounds were caused to undergo dissociation by the addition of a large excess of one of their constituent metals.*

In conclusion it may be added that the writer² has recently succeeded in showing, by means of the diffusion method already referred to, that, in mercurial solutions of these metals, the compounds present very probably correspond to the following formulas, in which, it will be noted, each compound contains but one atom of the amalgamated metal to the molecule: LiHg_3 , NaHg_5 , KHg_8 , RbHg_6 , CsHg_6 , CaHg_5 , SrHg_6 , and BaHg_6 .³

URBANA, ILL.

¹ The solution tensions of these metals in their amalgams are best explained as being due to the presence of their free monatomic molecules in the mercurial solutions; these metals are present in the mercury either wholly in the free state, or only partially so. In the latter event, we have the equilibrium: $\text{MeHg}_n \rightleftharpoons \text{Me} + n\text{Hg}$; and in dilute liquid amalgams mercury is present in such great excess, that $(\text{Me})/(\text{MeHg}_n) = \text{const.}$; that is, in the case of a given metal, C_{Me} , and therefore P_{Me} , is proportional to the total concentration of the metal in the dilute solution.

But, for the different metals in their dilute equimolal mercurial solutions, the different values of $(\text{Me})/(\text{MeHg}_n)$ depend upon the different degrees of dissociation of the compounds, MeHg_n , and these in turn depend upon the different affinities of the metals for mercury.

² *THIS JOURNAL*, **36**, 859 (1914); *Z. anorg. Chem.*, **88**, 161 (1914).

³ The crystals of the approximate composition KHg_{12} , etc., which have been mentioned in the literature (cf. e. g., Kerp and Böttger, *Z. anorg. Chem.*, **25**, 1 (1900); Smith and Bennett, *THIS JOURNAL*, **32**, 622 (1910)), are probably solid, or semi-solid solutions of the above compounds with mercury.

A NEW THERMOCHEMICAL METHOD FOR SUBDIVIDING ACCURATELY A GIVEN INTERVAL ON THE THERMOMETER SCALE.

BY THEODORE W. RICHARDS AND THORBERGUR THORVALDSON.

Received November 16, 1914.

Heretofore the scientific world has relied primarily for its exact temperature scale upon the careful study of the expansion of hydrogen made at the Bureau des Poids et des Mesures. The reduction of this hydrogen scale to the true thermodynamic scale has been the subject of much interesting discussion.¹ But for several reasons, which need not be amplified here, the outcome is not wholly satisfactory, hence new methods of fixing the standard scale are earnestly desired. The linear temperature coefficient of the electrical conductivity of platinum is being strongly advocated by some as the standard, and seems at present to possess several advantages.² Nevertheless, this is no reason for withholding other suggestions; and, accordingly, the present paper describes an entirely new method of subdividing a small interval, which relies upon a thermochemical application of the first law of thermodynamics.

We were led to this method by inconsistencies amounting sometimes to over half of 1% in accurately conducted thermochemical experiments. These were numerous, involving heats of combustion, heats of dilution, heats of neutralization, and heats of solution of metals. The cause of the trouble might have been either (a) in experimental error, (b) in the thermodynamic reasoning involved, (c) in the measurement of the heat capacities or (d) in the measurement of the temperatures; but careful study led us to reject alternatives (a), (b) and (c). Accordingly, (d), only, remained; i. e., the temperature scale must be in error. The irregularities were of such a character as to seem to show that the 18°-point on our standard thermometers (which had been calibrated with considerable care in Paris) was not exactly half-way thermodynamically between the 16° and the 20° point.

Therefore, it occurred to us that phenomena capable of showing such an inconsistency could be used, working backwards, to calibrate the thermometers; and, accordingly, a very simple reaction was chosen for this purpose. The problem was simply to conduct this reaction at various temperatures, in such a way that the final temperature of one trial should be the initial temperature of the next, thus covering the whole interval to be

¹ See for example, E. Buckingham, Bureau of Standards, Reprint No. 57 (Vol. 3, 1907). Burgess, *J. Chim. Phys.*, 11, 529 (1913).

² Jaeger and von Steinwehr, *Ann. der Phys.*, [4] 43, 1165 (1914) and others.

studied step by step in a way analogous to the Ostwald calibrator for a buret.

The heat of dilution of hydrochloric acid was chosen, on account of its ease of measurement, its easily regulated magnitude, and the comparatively simple nature of the heat-capacity problem involved. The acid was diluted calorimetrically in an apparatus described in detail in a previous paper;¹ the device was found to give very consistent and satisfactory results. By choice of varying initial concentrations of acid and of varying final concentrations, one can obtain at will a temperature-change anywhere from a few thousandths to several tenths of a degree—exactly such ranges as are likely to be required.

In the case to be described, acid of the precise concentration $\text{HCl} \cdot 20\text{H}_2\text{O}$ (9.18% or about 2.64 normal) was diluted with exactly 80 H_2O , causing it to become about 0.57 normal. This reaction gives enough heat to raise the total amount of liquid about 0.25° , a very convenient interval to use as a sort of thermodynamic yard-stick in subdividing the interval of 4° needed in thermochemical investigations.

Sixteen successive temperature increments during the dilution of successive portions of this sort, covering the whole scale between 16° and 20° , were as follows after correction for the heat of stirring (0.0005° per experiment): 0.2505° , 0.2520° , 0.2535° , 0.2535° , 0.2550° , 0.2550° , 0.2565° , 0.2575° , 0.2585° , 0.2575° , 0.2590° , 0.2585° , 0.2600° , 0.2595° , 0.2615° , 0.2605° . All these temperatures are given in terms of a standard scale, obtained after due correction from carefully standardized thermometers of excellent manufacture. It is evident that whereas at first the rise of temperature in the reaction seemed to have a temperature-coefficient of nearly 0.004° per degree, toward the end it seemed to possess no temperature-coefficient at all. This irregular performance suggests at once that something must be wrong with the thermometric scale; and the deviations are precisely in the same direction, and of the same order of magnitude as the earlier inconsistencies which led to this work.

If the heat capacity of the reacting substances remained unchanged during the dilution, the heat of dilution would remain constant, over the whole range, according to the well-known law of Kirchhoff.² In that case, the deviations of each of the numbers just given from their average would give at once the error of each number, and therefore the correction which should be applied to the thermometric readings over each short range. But with the particular reaction in question, this is not the case; the heat capacity of the system really diminishes appreciably during the reaction, and accordingly the heat of reaction increases appreciably

¹ Richards, Rowe and Burgess, *THIS JOURNAL*, **32**, 1179 (1910).

² See, for example, Richards, *THIS JOURNAL*, **25**, 209 (1903).

as the temperature rises. This increase is to be found by actually measuring the heat capacities of the factors and products—a measurement from which errors of the thermometer may be wholly eliminated by making the determination over the same range in each case. In this way it was determined that the heat capacity of $\text{HCl} \cdot 20\text{H}_2\text{O} + 80\text{H}_2\text{O}$ is 1778.5 and that of $\text{HCl} \cdot 100\text{H}_2\text{O}$ is 1772.3 (if the heat capacity of a gram of water is unity)—a loss of 6.2 calorie units of heat capacity during the reaction.¹ This signifies that the heat of dilution increases 0.00348° per degree, or 0.00087° for the quarter-degree interval between successive trials.² The value of the temperature-increment thus found for each stage of the dilution only holds exactly, however, in the ideal case in which (a) the apparatus, used for dilution has no heat capacity; (b), the change of heat capacity has no temperature-coefficient; and also when (c), the standard of reference of heat capacity (water), is likewise unchangeable over the total range concerned. The first and the last of these conditions obviously do not hold in the present case; but, fortunately, each is a matter susceptible of experimental solution. For: (a), the heat capacity of the apparatus, is easily calculated (in our experiments it was 1.643% of the total); (b), the change of heat capacity was found by actual measurement to be very nearly independent of temperatures between 16° and 20° ;³ again (c), the specific heat of the standard (water), has been determined by Barnes with great care by means of a platinum resistance thermometer (in a way practically independent of the hydrogen thermometer) to be 1.00105 at 16° if the value at 20° is taken as unity.⁴ This latter change is slight, amounting to only 0.000016° for each stage of the dilution—a relatively small proportion of the whole. In this case it almost exactly balances correction a. Correcting for these three minor influences, the theoretical increase in the temperature of each heat of dilution is found to be 0.00087° . If now we assume, as a preliminary step, that the first dilution should have given 0.25027° as its correct temperature rise, the successive theoretical heats of dilution will progress regularly as follows: 0.25027° , 0.2511° , 0.2624° , 0.2633° . The difference between each of

¹ These determinations were carefully made but they cannot be considered as more than preliminary ones; the details will be recorded in another place.

² Each rise of temperature due to heat of dilution was a trifle over the quarter of a degree, but they overlapped by a few thousandths of a degree, so that the 16 intervals really covered almost exactly 4° . The slight overlapping does not introduce any perceptible error.

³ If this is later found not to hold precisely, due correction can easily be applied.

⁴ N. B.—Although there may be some doubt about the *absolute* value of the specific heat of water, the *slope* of the curve at this point is probably quite near enough the true value for our present purpose. See Barnes, *Phil. Trans. (A)*, 199, 149 (1902).

⁵ This number was chosen by trial because it makes the correction at 20° the same as at 16° ; it assumes that this interval is indeed exactly 4.0000° .

these sixteen calculated values and the corresponding sixteen actual measurements mentioned on page 82, line 21, will give the error of the thermometer's reading over each of the short ranges, and the sum of all these partial errors down to any desired point will be the total errors to that point. In this way, the thermometric errors depicted in the following diagram were found in the special case chosen as an example, the values being plotted as ordinates, and the thermometer readings as abscissae.

Of course, since this is merely a relative matter, any one of the temperatures may be assumed as the standard of reference for these errors. As drawn, it was assumed that the correction at 17.14° was zero, in order to have about as many of the errors positive as negative; the reason of this choice will appear shortly. The shifting of the standard of reference shifts the whole curve bodily up or down, without affecting the algebraic

Fig. 1.—Errors of the thermometric scale in question. Scale readings are plotted as abscissae; errors (in thousandths of a degree) as ordinates.

differences of the corrections. For practical purposes it would be more convenient and less confusing to invert the curve (because a *plus* error means a *minus* correction) and to assume the lowest point of the resulting curve (18.25 in this case) as zero, so that all the corrections would be positive, and could be added directly to the thermometer reading.

A definite arbitrary change in the magnitude of the initial standard interval (in this case 0.25027) would change the general slant of the curve without altering its general character. Such a change alters the fundamental interval covering the whole range, and each part of this interval proportionately. The value 0.25027 was chosen because then the correction at 20° becomes the same as that at 16° , as already stated.

On the other hand, a change in the *increment* of the standard interval alters the character of the curve. This change is not arbitrary, but depends upon the measurements of the heat capacity, which must be executed with accuracy. It may be shown that the same actual degree of nicety is needed in this part of the work as in the work concerning the heat of

dilution, but lack of space forbids the detailed explanation. If the final curve is to have an accuracy in every part of 0.0005° , the change of heat capacity must be known to within about 0.25 calorie unit, which corresponds to an error of 0.001° over an experimental range of 4° , supposing that the calorimeter holds a liter of liquid.

It will be noted that this method does not attempt to fix the value of the standard interval with reference to the whole range $0-100^\circ$. The method gives only a means of *subdividing* any interval chosen as a standard (in this case the four degrees between 16° and 20°). To cover the whole range one would be required to carry out dilution experiments (or some other well-studied reaction) over the whole range. On the other hand, the method does provide a method for calibrating thermochemical thermometers, possessing just the degree of accuracy which is needed for thermochemical purposes.

The dilutions recorded in the special case above were verified by a similar series with a smaller rise of temperature (0.22), diluting $\text{HCl} \cdot 20\text{H}_2\text{O}$ to $\text{HCl} \cdot 121.5\text{H}_2\text{O}$. The curve in this series showed essentially the same features as the other, and need not be given in detail.

The shape of this curve given above is of more than passing interest, because it tells of corrections to be applied to the scale of a thermometer assumed to be trustworthy—the best that could be furnished a decade ago from a supposedly competent source. On the whole, it is seen to support the excellent work of the maker and of the standardizer; as recorded above, only one of the seventeen readings deviates more than 0.004° from its true value. But, nevertheless, the combined effect of these variations is a very serious matter, for the face-value of the interval between the true 16.000° and 18.000° is 2.007° , whereas between 18.000° and 20.000° is only 1.993° . In other words, there will be a discrepancy of 0.7% between the results obtained respectively over these two ranges: a very serious matter in accurate work. It was just such discrepancies which led to the undertaking of this new method; and it is pleasant to find that the new temperature scale removes many if not all of these discrepancies. But the chronicle of these details must be reserved for later communications. The question as to whether the errors are due merely to peculiarity in our standard thermometers, or are to be ascribed to the standard to which they in turn were referred, must be left to future research.

The results recorded above are only preliminary. The most difficult part of the performance (namely, the determination of the heat capacities of factors and products) can be determined once for all with great accuracy, and these figures can then be used by anyone, in any part of the world, for the computation of his results. The work required for the verification

of any thermometer will then consist simply in a series of dilutions (sixteen are obviously needed to cover 4° in 0.25° steps). This experimental work is very easily done, and with the adiabatic calorimeter is capable of great accuracy. Of course other reactions also, besides the heat of dilution of hydrochloric acid, could be used for this purpose, after they had been properly studied. Heat of neutralization of acids may be especially convenient. In case any interval appeared to be especially abnormal, it could be subdivided still further by a yet feebler reaction. We have already made further progress along these lines, and hope soon to publish a more complete account, which we hope may be really useful to chemists and physicists dealing with the difficult subject of exact thermometry.

We are greatly indebted to the Carnegie Institution of Washington, whose liberal grant alone made the work possible at this time.

Summary.

A new method for subdividing accurately any given interval on the thermometer scale is presented. This method depends upon the execution of a given simple reaction step by step over the range in question, somewhat analogously to the calibration of a buret with the Ostwald calibrator. Allowance must be made, of course, for the temperature-coefficient of the reaction, and other details dependent upon changing heat-capacity. The method is peculiarly suitable for the standardizing of short ranges, such as those used in thermochemistry.

THE SEPARATION OF TUNGSTEN FROM MOLYBDENUM.¹

BY EDWARD ELLSWORTH MARBAKER.

Received October 8, 1914.

With the extensive introduction of tungsten and molybdenum into industrial chemistry in the form of the special steels and the filament of the incandescent electric lamp, the importance of these metals has been greatly increased from the standpoint of the analytical chemist.

It is a well-known fact that molybdenum always accompanies tungsten in its ores, and it shows a marked tendency to remain with the tungsten throughout the process of manufacture. This amount of molybdenum, although small, interferes to a great extent with the determination of the tungsten, and hence one of the important problems in modern analysis is to devise a separation of the two metals which will be easy to carry out and also be of the highest accuracy. Up to the present time there have

¹ From the author's Ph.D. thesis, 1914.

been suggested methods for the attainment of this end: Rose,¹ Pechard,² Smith and Reugenberg,³ Ibbotson and Brearley.⁴ In 1911, Mdivani⁵ announced a new method for the determination of tungsten which was based on the observation of Anthon,⁶ that when a tungstate solution is treated with a solution of stannous chloride, a yellow precipitate of normal tin tungstate, SnWO_4 , is formed, which is changed to the blue oxide of tungsten, W_2O_5 , on the addition of concentrated hydrochloric acid. Mdivani added to the tungstate solution, a solution of stannous chloride in concentrated hydrochloric acid and then boiled for a few minutes. The blue oxide was precipitated and, after settling, was filtered off, washed with hot water, dried, ignited to tungsten trioxide and weighed as such.

I. An Effort to Reproduce the Results of Mdivani.

Mdivani made up a solution for analysis by dissolving 2 g. of pure tungsten trioxide in strong ammonia and diluting to one liter. He treated 50 cc. of this solution, which contained 0.1 g. of WO_3 , with 20 cc. of a solution containing 50 g. of crystallized stannous chloride in 200 cc. concentrated hydrochloric acid. The blue precipitate which was thrown down was boiled up for a few minutes and then allowed to settle, after which it was washed by decantation with hot distilled water and finally ignited and weighed as tungsten trioxide.

A weighed sample of pure tungstic acid, which had been prepared for the purpose of making ductile tungsten lamp filament; was treated with strong ammonia. The attack was not complete, showing that the purity of the substance was doubtful; but the solution was filtered and made up to one liter. Samples of this solution were analyzed by evaporating to dryness three times with hydrochloric acid and nitric acid, baking at about 120° for fifteen minutes after each evaporation, then washing on to a filter with a hot ammonium nitrate solution, finally igniting and weighing. Fifty cc. of the solution were thus found to contain 0.1422 g. WO_3 . This value was obtained as the average of ten closely agreeing determinations.

A solution of stannous chloride was made according to the directions of Mdivani. Twenty cc. of the tin solution were added to 50 cc. of the ammonium tungstate solution, and the resulting blue precipitate was boiled for a few minutes and washed according to the directions of Mdivani. The pure water recommended for washing was found to be inadequate because it caused the formation of basic tin salts which could not be

⁶ Anthon, Dammer, *Handbuch*, 3, 659 (1893); *J. prakt. Chem.*, 9, 341 (1836).

washed out and hence gave rise to high results. This was easily remedied by washing the precipitates with a solution of hydrochloric acid made by adding 50 cc. of strong acid to a liter of boiling distilled water. The washed precipitates were thus entirely free from tin.

Four determinations resulted as follows:

WO₃ present, 0.1422 g.; WO₃ found, 0.1392, 0.1386, 0.1390 and 0.1387 g.

To determine the cause of these low results, the filtrate from one of the determinations, which was perfectly clear and colorless, was evaporated to dryness. Blue oxide of tungsten separated. This showed that either the precipitation had not been complete or that the acid of the wash water had caused some of the oxide to pass into solution. Subsequent results indicated that the latter was not the case. The small amount of blue oxide was transferred to a filter and washed with the dilute acid until the filtrate gave no test for tin on the addition of ammonia. The filter and its contents were then ignited, but instead of obtaining a small amount of yellow tungsten trioxide, there was present a mixture of the yellow oxide and a white substance which proved to be tin oxide. This would indicate that a combination had taken place between the tin and the tungsten, because all of the tin had been washed out of the precipitate so far as the tests on the filtrate showed. In order to eliminate the small amount of tin, the residue was carefully treated with ammonium chloride, as recommended by Rammelsberg,¹ which causes the tin to volatilize as stannic chloride, leaving the tungstic acid behind. The weight of this residue added to that of the main portion of the oxide brought the result into agreement with the theoretical.

2. The Action of Mdivani's Reagent on a Mixture of Ammonium Tungstate and Ammonium Molybdate.

When stannous chloride was added to a solution of ammonium molybdate a brown precipitate appeared. This rapidly dissolved in the excess of the reagent, the solution assuming a characteristic orange color, due to the reduction of the MoO₃ to Mo₂O₃. This is very different from the reaction which takes place in the tungstate solution, hence it seemed possible to effect a separation.

A solution of molybdenum trioxide in ammonia was made up and analyzed by the method of Chatard.² Ten cc. of the solution were found to contain 0.1164 g. MoO₃.

A solution containing 0.1164 g. MoO₃ and 0.1422 g. WO₃ was treated with 20 cc. of the tin solution and the resulting precipitate of W₂O₆ handled as outlined before. It was washed with the acid wash water until the washings gave no test for tin. The filter and its contents were ignited and weighed. A fairly close value for the tungsten was obtained.

¹ Rammelsberg, *Chem. News*, 9, 25 (1864).

² Chatard, *Ibid.*, 24, 295 (1871).

It was assumed at this point that the precipitate of tungstic acid contained no molybdenum, but a careful test was made to determine whether the filtrate containing the molybdenum contained any tungsten. This test was carried out as follows: An excess of metallic zinc was added to the solution and the tin was precipitated as metal. The solution changed color from orange to green. It was decanted from the tin, which was present in the form of a porous cake, and the tin washed several times with hot water. The clear green liquid was then evaporated on the hot plate, during which process the color changed to brown again. When the bulk of the solution had been decreased to about 150 cc. a few drops of nitric acid were added. It rapidly became colorless, showing that the molybdenum had been oxidized to the form of molybdate. Ammonia was then added in great excess. The precipitate of zinc hydroxide which first appeared dissolved in excess, leaving a small precipitate of iron and tin hydroxides. This was filtered out and reprecipitated. The filtrate was added to the main solution and the whole treated with acid to the point of neutrality. A small amount (3-5 cc.) of acetic acid was then added, followed by an excess of lead acetate. A precipitate of lead molybdate was formed which after settling, was filtered, washed with dilute acetic acid, ignited and weighed. This weight proved to be lower than the theoretical but the loss could not be accounted for, although the precipitate of tin metal, the iron and tin precipitate, and the filtrate from the lead molybdate were all tested with zinc and sulfocyanide, but no evidence of molybdenum was observed.

The ignited residue of lead molybdate was then tested with hydrochloric acid, according to the method of separation suggested by Ibbotson and Brearley.¹ The solution of the residue was complete, but on dilution no tungstic acid separated out, thus showing that the molybdenum was not contaminated with any tungsten and that, so far as the tungsten was concerned, the separation was complete.

It was found in other determinations, carried out in the same way, that the weight of the tungstic oxide was high, although all the tin had been removed by careful washing. The high results must then have been due to a small amount of molybdenum left in the tungsten. The precipitate of W_2O_5 was dissolved in ammonia containing a little hydrogen peroxide and reprecipitated with a second portion of the tin solution. The precipitation at this point was never complete, because the filtrate had a blue color. This was evaporated to dryness, the W_2O_5 washed out and ignited with ammonium chloride and finally weighed. This weight was added to that of the main precipitate and the sum of the two gave a somewhat low result, due probably to unavoidable losses in the process of analysis.

¹ Ibbotson and Brearley, *Chem. News*, 81, 13 (1900).

A series of results follows:

Gram WO_3 present.	Gram WO_3 found.	Gram WO_3 present.		Gram WO_3 found.
0.1422	0.1426	0.1422	Reprecipitated	0.1412
0.1422	0.1414	0.1422		0.1405
0.1422	0.1429	0.1422		0.1414
0.1422	0.1434	0.1422		0.1434
0.1422	0.1432	0.1422		0.1428
0.1422	Reprecipitated 0.1404	0.1422		0.1415

Average, 0.1422

These results indicate a possible separation of tungsten from molybdenum, although they are not particularly concordant. The molybdenum was not determined, because at the moment there was no method available for the separation of the molybdenum from extremely large amounts of tin.

3. The Action of Mdivani's Reagent on a Mixture of Sodium Tungstate and Sodium Molybdate.

Mdivani states in his paper that the quantitative precipitation of tungsten may be carried out as well in solutions of sodium and potassium tungstate and molybdate as in solutions of the ammonium salts.

The solution of sodium tungstate used was made from a portion of the salt which had been prepared by fusing together the theoretical amounts of pure WO_3 and Na_2CO_3 and crystallizing the product. The solution contained 0.1489 g. WO_3 in each 10 cc. The solution of sodium molybdate was made by dissolving a sample of a salt, which had been made by Schuchardt, and afterwards recrystallized several times. This solution contained 0.1200 g. MoO_3 in each 10 cc.

A sample of the tungstate solution was measured out and treated with the usual amount of Mdivani's reagent. The blue precipitate appeared and was filtered off. The filtrate was colored blue, showing that the precipitation had not been complete. Several attempts were made to improve this precipitation by adding more reagent than usual and also by the addition of ammonium chloride, but without any favorable results.

A solution containing both tungstate and molybdate was then treated in the usual manner with the tin solution in order to determine the effect of the presence of sodium molybdate. The blue precipitate of W_2O_5 came down well and was weighed after filtering and washing. The filtrate in this case was orange colored, on account of the molybdenum present. A series of ten determinations was made and the results were so concordant and near the theoretical that it shows conclusively that for the amounts of tungstate and molybdate present a separation of tungsten and molybdenum can be effected by means of an acid stannous chloride solution. The results follow:

Gram MoO ₃ present.	Gram WO ₃ present.	Gram WO ₃ found.
0.1200	0.1489	0.1492
0.1200	0.1489	0.1489
0.1200	0.1489	0.1490
0.1200	0.1489	0.1486
0.1200	0.1489	0.1486
0.1200	0.1489	0.1489
0.1200	0.1489	0.1492
0.1200	0.1489	0.1486
0.1200	0.1489	0.1489
0.1200	0.1489	0.1489

As in the case of the separation of tungsten and molybdenum using the ammonium salts, the molybdenum was not determined.

The tungsten trioxide obtained in the foregoing analyses was tested for molybdenum by the method of Debray¹ by passing over it dry hydrogen chloride at a temperature of 200°. A slight sublimate of the compound MoO₃.2HCl was formed, proving that a little molybdenum was present. On subsequent analysis by the method of Chatard it was found that the molybdenum contained in the tungsten trioxide from six determinations amounted to less than one milligram of MoO₃.

The fact that the separation takes place so easily is so at variance with the usual experience of analysts of tungsten compounds that it seemed very remarkable that the molybdate actually aids the precipitation of the tungsten, as it will be remembered that the precipitation of W₂O₆ from the tungstate alone is never complete. This was so peculiar that the effect of other salts on the precipitation was tried. The results of these tests were as follows:

Salt present.	Gram WO ₃ present	Gram WO ₃ found.
0.1 g. K ₂ SO ₄	0.1489	0.1481
0.1 g. K ₂ SO ₄	0.1489	0.1488
K ₂ CrO ₄	0.1415	0.1414
0.2 g. NaCl.....	0.1489	0.1487
0.2 g. NaCl.....	0.1489	0.1494

The filtrate from the tungsten in all of the foregoing determinations, except that containing chromium, was perfectly colorless. These results show that an accurate estimation of the tungsten in sodium tungstate can be made by the addition of any of the salts mentioned in the table.

In order to determine the availability of the method various amounts of sodium tungstate and sodium molybdate were taken. The results appear in the following table:

Gram MoO ₃ present.	Gram WO ₃ present.	Gram WO ₃ found.
0.1200	0.0089	0.0089
0.1200	0.0149	0.0151
0.1200	0.0596	0.0592
0.1200	0.0900	0.0900

4. The Determination of the Molybdenum in the Filtrate from the Blue Oxide.

The filtrate from the tungsten contains all the molybdenum and a large amount of tin in the form of stannous and stannic chlorides. The tin was removed from the solution by means of metallic zinc, the filtrate was evaporated down to a small bulk, oxidized with nitric acid and treated with an excess of ammonia. The zinc hydroxide which was thrown down dissolved in excess. The molybdenum was then precipitated by lead acetate after the solution had been almost neutralized with HCl and finally treated with a small excess of acetic acid. The precipitate of lead molybdate was allowed to settle, filtered, washed with hot dilute acetic acid, and finally weighed. In every case the result was low.

Since the foregoing procedure failed to solve the problem of determining the molybdenum, a careful review of the literature was taken up in the hope that a method for determining molybdenum in a hydrochloric acid solution had been devised. Nothing of this nature was found in connection with any gravimetric method, but the discussion of the volumetric methods seemed to offer a means of solving the problem.

Randall¹ has shown that when a molybdate solution is passed through a Jones reductor and the reduced solution is caught in a ferric ammonium sulfate solution, decolorized by phosphoric acid, that the ferric iron oxidizes the molybdenum, and the ferrous iron thus formed may be titrated with standard potassium permanganate. This investigator proved that the molybdenum is completely reduced to the form of Mo₂O₃. Accordingly, a determination was carried out as follows: A portion of the sodium molybdate solution was measured out and treated with about 20 cc. of Mdivani's reagent. This gave rise to an orange colored solution, to which were added about 5 g. of pure 20-mesh zinc. The tin was deposited on the zinc as metal, and the green supernatant liquid was poured off, the tin washed with hot water, and then the solution and washings were heated to about 60°.

The reductor flask was charged with 20 cc. of the ferric alum solution

¹ Randall, *Am. J. Sci.*, [4] 24, 313 (1907).

and 20 cc. of the "titrating solution."¹ Fifty cc. of dilute hydrochloric acid (2.5% by vol. of the concentrated acid heated to 60°) were passed through the reductor, followed by the solution containing the molybdenum, and then 150 cc. of the warm acid and finally 150 cc. of hot distilled water.

The flask was removed from the reductor and the titration was carried out in the usual way with the permanganate² solution. The molybdenum solution before entering the reductor is green, while in the reductor the reduction is completed, although there is no noticeable change in color. When the green solution enters the ferric solution the color changes to red. This red solution is titrated with permanganate, but the red color offers no obstacle because, as the permanganate is added, this color disappears, and toward the end of the titration the color of the solution is a faint bluish green in which the end point is very easily seen. The end point has to be taken very quickly, as it is not at all permanent. However, the titration is one which is very easily carried out.

A number of such determinations were made with the following results:

Gram MoO ₃ present.	Gram MoO ₃ found.	Gram MoO ₃ present.	Gram MoO ₃ found.
0.1500	0.1505	0.1350	0.1354
0.1500	0.1505	0.1635	0.1632
0.1470	0.1476	0.1200	0.1198
0.1500	0.1498	0.1050	0.1051
0.1500	0.1498	0.1800	0.1801

They show that the separation of tin from molybdenum by means of metallic zinc is quantitative and that the method may be used to determine the molybdenum in the filtrate from the tungsten in the method of separation under consideration.

5. The Separation of Tungsten from Molybdenum.

The two processes outlined in the third and fourth sections of this paper were combined, and both constituents of the mixture of sodium tungstate and molybdate were determined.

The separation worked very well with quantities up to and including 0.3000 g. of each constituent. More than this amount gave rise to high results unless an inordinate amount of time was consumed in washing out the molybdenum from the tungsten. The high results can be more quickly corrected by treating the ignited residue of WO₃ with as many cc. of concentrated hydrochloric acid as there are centigrams of the residue and boiling for a few minutes. Then this may be diluted with three times its volume of hot water and allowed to settle. This process removes the contaminating molybdenum and leaves the tungsten pure. The filtrate containing the small amount of molybdenum is of course

¹ This consisted of 90 g. manganous sulfate, 650 cc. distilled water, 175 cc. syrupy phosphoric acid and 175 cc. concentrated sulfuric acid.

² Standardized against ferrous ammonium sulfate and also oxalic acid.

added to the main molybdenum solution. There seem to be no limits to the applicability of the molybdenum titration. When large amounts of molybdenum were present it was found advisable to make up to 250 cc. and work with portions of 50 cc. each. The latter method proved to be a great factor in reducing the time of the determination.

When moderate samples are used the whole process, involving the determination of both the constituents, can be carried out in about three hours. The greater part of this time is consumed in washing the tungsten precipitate and in evaporating the filtrate containing the molybdenum to a bulk which may be easily handled.

The results of ten complete separations follow:

Gram WO_3 present.	Gram MoO_3 present.	Gram WO_3 found.	Gram MoO_3 found.
0.1005	0.1005	0.1001	0.1010
0.1500	0.1500	0.1496	0.1498

0.3000	0.3000	0.3000	0.2996

Summary.

Tungsten and molybdenum, in the form of their sodium salts, may be quickly and easily separated, the course of analysis being as follows:

To a boiling solution containing the tungstate and molybdate of sodium in appropriate amounts add the tin solution (50 g. $SnCl_2 \cdot 2H_2O$ dissolved in 200 cc. concentrated HCl) in the proportion of 20 cc. for each 0.15 g. WO_3 present. This amount of the reagent should be carefully regulated, because less will not effect a complete separation, and more will be correspondingly harder to handle in the determination of the molybdenum. The dilution of the solution for analysis should be kept between 60 cc. and 300 cc., depending on the amount of tungsten present. After boiling a few minutes allow the blue precipitate of W_2O_5 to settle and then pour the orange supernatant liquid through a filter. Wash the precipitate thoroughly by decantation with hot 5% hydrochloric acid until the washings give no test for molybdenum by the zinc and thiocyanate method. Bring the precipitate on the filter and allow to drain. If the amount of precipitate is small the filter may be ignited wet, but if the amount be large it is better to heat it until the greater part of the water has been driven off. Place the filter in a porcelain crucible and ignite gently to WO_3 . Cool in a desiccator and weigh.

The filtrate and wash water are united and the whole evaporated to a small bulk. If the amount of tungsten and molybdenum taken has been

large, cool and dilute to 250 cc. and use aliquot portions of 50 cc. To this solution add from 5-10 g. of 20 mesh zinc. The tin will come out as metal. Pour off the green solutions when the precipitation of the tin is complete (this takes about ten minutes), and wash the cake of tin several times with hot water. Unite the filtrate and wash water and heat to 60°. Pass through the reductor in the order named, 50 cc. dilute HCl,¹ the solution containing the molybdenum, 150 cc. 2.5% (vol. conc. HCl), and finally 150 cc. hot distilled water. These pass into the flask of the reductor, which has been previously charged with 20 cc. 10% ferric ammonium sulfate and 20 cc. of the "titrating solution." This solution is next titrated with approximately 0.1 N potassium permanganate and the amount required calculated to MoO₃.

If it is desired to determine the amount of tungsten in a sodium tungstate solution, add to that solution a quantity of sodium chloride solution, and proceed as when molybdenum is present.

A fairly accurate separation of tungsten and molybdenum may be effected when they are present as ammonium salts, but the method is not to be highly recommended.

THE MOLECULAR WEIGHT OF SODIUM CARBONATE AND THE ATOMIC WEIGHT OF CARBON REFERRED TO SILVER AND BROMINE.

By THEODORE W. RICHARDS AND CHARLES R. HOOVER.

Received November 19, 1914.

Investigations concerning radioactivity have increased rather than diminished the interest in atomic weights. The possibility indicated by recent research that variations in these figures may exist in radioactive elements² stimulates further research in all directions concerning these quantities; for such variations cannot be due to chance, but must have fundamental cause. To be sure, no valid evidence of variation in any value except that for lead has as yet been found; but whether or not the atomic weights vary in a few cases, they still probably remain the most fundamental figures which come within our scientific ken. Therefore, no amount of trouble is too great to secure complete and satisfactory knowledge of them.

¹ Containing 2.5% by volume of the strong acid.

² Richards and Lemberg, *THIS JOURNAL*, 36, 1329 (1914); also *Z. anorg. Chem.*, 88, 429 (1914), and *Science* (June 5, 1914), p. 831. This conclusion has been supported also by Soddy (*Proc. Chem. Soc.*, 30, 134 (1914)), by Maurice Curie (*Compt. rend.*, 158, 1676 (1914)), and by Hönigschmid and Mlle. S. Horovitz (*Ibid.*, p. 1786); also *Z. Electrochem.*, 20, 319 (1914).

It is well recognized by everyone conversant with this matter that as many different methods as possible for determining each atomic weight should be employed. F. W. Clarke has often emphasized this point. The difficulty in carrying out this recommendation is that so few substances lend themselves to accurate analysis. Crystalline precipitates always carry down some of the mother liquor from which they were prepared, and hence many usual analytical methods are not permissible, when great accuracy is required. For this reason, and so as to get consistent and comparable results with different metals, the analysis of the chlorides and bromides has been one of the chief methods employed at Harvard—because the spongy nature of the silver halides makes it possible to wash them with unusual thoroughness. But some means of verifying these results by comparison with an entirely different standard would be highly welcome. For this purpose a new process, involving cross-reference, has recently been carried out in the Wolcott Gibbs Memorial Laboratory; and the present paper describes this new method of attack.

The plan was simply this: the purest sodium carbonate was to be weighed with scrupulous care, dissolved in water, and exactly neutralized with hydrobromic acid. The amount of silver necessary to precipitate this hydrobromic acid was then to be determined by the usual process. In this way the chemical equivalence between the weights of sodium carbonate and silver could be simply determined, and the silver halide standard referred directly to an entirely new substance, namely, sodium carbonate. The accuracy of the process turned, of course, upon obvious criteria: first, the purity of the sodium carbonate and hydrobromic acid; secondly, the complete and exact neutralization without loss of material; and thirdly, the purity of the silver. The sodium carbonate, silver and silver bromide alone were weighed; but the hydrobromic acid obviously had to be prepared in a state free from every trace of other acids as well as from bases. As will be seen, the outcome was very satisfactory.

Preparation of Materials.

In an investigation of this kind the details of experimentation are of the utmost importance, therefore the necessary minutiae are given below.

Three different specimens of sodium carbonate were prepared: the first simply by many recrystallizations from water in platinum vessels; the second from recrystallized hydroxide made by the reaction of sodium bromide on silver oxide; and the third from sodium amalgam electrolytically produced from hydroxide resulting from the reaction of barium hydroxide on sodium sulfate. In making the first sample 3 kg. of "C. P." sodium carbonate were dissolved in pure water, filtered while cold through hardened filter paper, and at first recrystallized four times from pure water in porcelain dishes with centrifugal washing and draining.

The solution of the crystals was again filtered, as before, through washed filter paper, and recrystallized five times in platinum vessels, again with centrifugal draining and washing. The solution of this ninth crop of crystals was finally filtered through the platinum mat of a carefully prepared Gooch-Munroe crucible, and recrystallized, making ten crystallizations in all. The last crop of crystals, contained in a platinum dish, was dehydrated in a vacuum desiccator over fused sodium hydroxide, and was called Sample A.

As briefly suggested above, the second sample B was prepared in a very different way. Sodium hydroxide (previously twice recrystallized) was added in excess to twice recrystallized silver nitrate. The washed precipitate of oxide was treated with a solution of sodium bromide which had been five times recrystallized as hydrate. The resulting sodium hydroxide solution was then once recrystallized from concentrated solution by strong cooling, and was transformed into sodium carbonate by passing pure carbon dioxide into the solution through an inverted platinum funnel. The solution was filtered through a platinum mat, and the salt was thrice crystallized. All these operations were carried out in platinum, except the crystallization of sodium hydroxide, which was carried out in silver.

For the sake of especial care, the preparation of the third sample, C, involved yet different processes. Sodium sulfate was added in slight excess to barium hydroxide, each having been previously four times recrystallized. The solution was decanted from the precipitate through a platinum filter and the resulting sodium hydroxide crystallized by cooling. A solution of this sodium hydroxide was electrolyzed in an amalgamated iron dish. The solid amalgam, after thorough washing, was partly decomposed by water, and the solution was evaporated to crystallization. The pure caustic alkali was transformed into carbonate as in the case of Sample 2, and the salt thus obtained was thrice recrystallized. All operations, except the electrolysis in the iron dish, were carried out in platinum or silver.

The hydrobromic acid was prepared from an especially pure sample of potassium bromate, which we owed to the kindness of Edward Mallinckrodt, Jr., of St. Louis. Three kilograms of this material (which showed only a trace of chlorine and no iodine) were three times recrystallized in porcelain; even the first crystals gave no test for chloride. Portions of the very pure product were decomposed to bromide by heating in platinum, and the bromide was fused. Proper quantities of bromate, bromide and very pure redistilled diluted sulfuric acid were gently heated in a glass-stoppered distilling flask. The pure bromine which distilled off was twice redistilled from the similar potassium bromide, and passed with hydrogen over hot platinized asbestos. The hydrobromic acid thus

formed was dissolved in pure water, concentrated, and three times redistilled through a quartz condenser.

Three samples of silver were used. The first was made from pure silver nitrate by a well tested method.¹ The salt, five times recrystallized, was reduced with ammonium formate prepared from redistilled ammonia and formic acid. The metal was thoroughly washed, dried and fused in hydrogen on a boat of pure lime made from six times recrystallized calcium nitrate. The buttons were then etched with nitric acid, washed with ammonia and much water, and dried at 400° in a vacuum.

The second sample was prepared with twice as much care, but appeared to be no purer. Silver nitrate, ten times recrystallized, was reduced in a silver dish with ammonium formate made by passing ammonia from redistilled ammonium hydroxide contained in a platinum retort into formic acid, twice redistilled in quartz, contained in a gold flask. The silver powder was washed many times with purest water, then fused and dried as in Sample 1.

A third sample of silver, prepared by Dr. H. H. Willard in our research on lithium perchlorate, was used in analyses Nos. 4 and 5.²

The quantitative identity of these three samples is evidence that all were as pure as possible.

In a research of this kind, involving exact neutralization, especial pains must be taken, not only with the solid substances concerned, but also especially with the water and gases which are employed. Water was thrice distilled, alkaline permanganate and a few drops of sulfuric acid being used in successive distillations, as usual. A thoroughly washed condenser of block tin was employed. Especial care was taken to exclude the products of combustion of the burners from the product. For much of the work, where carbon dioxide must be rigorously excluded, the water from the final distillation was condensed in such a way that it was collected cold in a stream of air wholly freed from carbon dioxide. The air used for this purpose, and in other cases where carbon dioxide must be excluded, was drawn direct from the vent supplying the filtered air to the laboratory before its entry into the room, and was washed and driven by a water blast through a long tube of copper oxide and through Emmerling towers containing, in succession, solution of copper sulfate, potassium permanganate dissolved in dilute very pure phosphoric acid, pure permanganate made alkaline by potassium hydroxide which had been fused to drive out volatile substance, and concentrated potassium hydroxide; then over solid, fused potassium hydroxide, and, finally, where it was

² Richards and Willard, Carnegie Inst. of Washington, Publication No. 125, 16 (1910), Sample A.

necessary to have especial purity and absence of moisture, over fused potassium hydroxide and resublimed phosphorus pentoxide, and over hot copper oxide, being filtered at last through a porous cup to retain dust particles.¹ The apparatus was, of course, constructed entirely of glass with fused or ground joints.

Carbon dioxide was generated in an Ostwald apparatus by the action of diluted, redistilled hydrochloric acid on selected pieces of pure marble. The gas was first passed through three towers containing sodium bicarbonate solution, and afterwards through three towers of boiled, concentrated sulfuric acid to which a trace of potassium dichromate had been added, and, finally, through a long U-tube of resublimed phosphorus pentoxide.

In one preliminary experiment nitrogen was used. This was prepared by the Wanklyn method of passing ammonia and air over heated copper. The apparatus for this purpose was kindly loaned us by Professor Baxter and Dr. C. J. Moore. Glass stopcocks were lubricated with a very small amount of a mixture of viscous paraffines containing a little pure melted rubber, as suggested by Ramsay. They were so arranged that either pure air or carbon dioxide could be passed, separately or mixed, through the familiar Harvard bottling apparatus;² and also when needed through vessels in which the solution of the sodium carbonate and the evaporation of the bromide were carried out.

Preparation of Sodium Carbonate for Analysis.

The almost anhydrous carbonate, after long drying in a desiccator over fused caustic alkali, was placed in a weighed platinum boat, covered with a piece of platinum foil, and heated gently in a quartz tube attached to the bottling apparatus. A removable mica sleeve wound with a thin ribbon of a commercial high-melting alloy furnished the necessary heat, with the help of a moderate electric current. After completing the dehydration, the platinum foil was removed and the boat and contents were heated for several hours at a gradually increasing temperature until the salt just fused, pure carbon dioxide being passed through the tube. As soon as fusion had taken place, the application of heat ceased and pure air was admitted, gradually decreasing the amount of carbon dioxide until, when the boat was cold, pure air was passing over it. The weight obtained this way was constant after successive trials, which was not the case when the salt was fused in nitrogen or air, a slight gain in weight being usually noted in the latter case. In the presence of air, at about 850°, fused sodium carbonate attacks platinum to a slight extent, especially if the salt is kept fused for a considerable time. Hoping to avoid this difficulty,

¹ Richards and Cox, *THIS JOURNAL*, 36, 819 (1914).

² Richards, Faraday Lect., *J. Chem. Soc.*, 99, 1203 (1911). See Richards and Parker, *Proc. Acad. Arts and Sciences*, 13, 86 (1897).

we used a gold boat in preliminary work, but this steadily gained in weight even after 60 hrs. treatment with nitric acid and prolonged ignition in air. Returning to the platinum boat, we found that in a stream of pure carbon dioxide free from air it was possible, by very gradually increasing the temperature until the salt was just fused, to prevent any significant action on the platinum boat. Thirteen fusions decreased the weight of the boat only 0.27 mg., or 0.02 mg. during each fusion.

There is reason to believe that sodium carbonate thus fused in a stream of pure carbon dioxide is purer than sodium carbonate prepared in any other way. The cooled mass could have contained no excess of carbon dioxide, since the vapor pressure of this gas from the bicarbonate at the temperature employed is enormous; moreover, because the salt came to constant weight on successive fusions, there is no suspicion of abnormal loss of carbon dioxide. Because we have been able to find no record of anyone's having prepared the salt in this way before, these samples were perhaps the purest specimens of it which have ever been made. Our experience shows that sodium carbonate, as ordinarily prepared for quantitative work, is not perfectly dry. Material heated at dull redness for a short time, as usual in most laboratories, was found to lose on fusion sometimes as much as 0.05% of moisture; and even after two hours of such heating the loss was about 0.03%. Material heated for a long time just below the fusion point lost on fusion only about 0.003%. The losses during our experiments ranged between these limits. It is true that for ordinary work such errors are immaterial; but in the most accurate work they become highly important.

The Solution and Quantitative Neutralization of the Sodium Carbonate.

Having been carefully weighed in the weighing bottle containing dry air, into which it was transferred in the bottling apparatus, the sodium carbonate was now dissolved and neutralized in pure, dilute hydrobromic acid. This solution was provided in carefully weighed quantity almost exactly necessary to neutralize about 5 g. of sodium carbonate, the amount usually employed in a determination. Because the method of dealing with this standard acid solution was somewhat unusual, a brief description is fitting.

Specially designed weighing burets containing the desired quantity of acid solution (about 200 cc.) were employed to weigh it. A large amount of the solution had been prepared shortly beforehand, and preserved in a bottle of resistant glass, from which it could be removed by a paraffin-coated and -lined glass syphon. Air was admitted to the bottle after passing through a U-tube containing a solution of the same nature and concentration as that in the bottle. When the buret was to be filled, after thorough agitation of the solution (which was at room temperature) a portion was drawn off sufficient to wash the interior of the syphon—

the last of this being added to the U-tube, replacing the solution which had previously been in the tube. Small portions of the acid solution were now run into the dry weighing buret, which was closed and gently shaken until it was thoroughly rinsed and filled with the vapor of the solution. The buret was then filled, with the syphon-tip inserted far into its interior, to avoid evaporation. Subsequently, the buret was carefully wiped with a slightly damp, perfectly clean linen cloth, and thereafter touched only with platinum forceps or linen cloth. After standing with the upper cock nearly closed in the balance case for one hour, the weight was taken by substitution, using a precisely similar, partly filled companion buret as substituting tare. Before filling a buret, the bottle containing the acid solution had been placed for some hours near the balance so that long waiting was unnecessary.

The required amount of solution was next removed from the buret and placed in the bowl of a very large platinum retort, the graduations upon the buret allowing one to determine to within 0.1 g. when the required weight had been removed. The buret was then returned to the balance case and in not less than an hour its weight was determined as before. It was found that three such complete manipulations could be carried out in succession; each consisting of weighing after one hour in the balance case, removing buret to the titration-room, replacing and removing the tip from the buret outlet, and reweighing, without any change in weight exceeding a milligram. As a rule, of course, in actual analysis, only one such operation was carried out.

As will be detailed, the concentration of this solution was exactly determined by reference to silver—the solution being weighed out for this purpose in successive portions just as for the neutralization; but, in order to not interrupt the narrative, the discussion of the neutralization will be continued.

As already stated, the exactly weighed acid solution was placed for the neutralization of the sodium carbonate into the body of a large platinum retort, very kindly given by Professor J. M. Crafts; and the weighed boat with the fused carbonate was carefully lowered into the solution. The tightly fitting cover was then placed on the retort, with the condenser tube attached; and the whole was set aside for some hours, usually overnight. The condenser tube was packed with scraps of platinum foil to serve as baffles, and the lower end placed into a gold flask which served to collect any solution projected in minute drops during the evolution of gas. When the fused salt was completely dissolved, the retort with condenser attached was very gradually warmed during several hours until at last boiling commenced. The supply of heat was then decreased and the condenser tube and gold flask were removed and rinsed into the retort, which was now covered, placed in an electric oven or bath, and warmed

while very pure air was passed in through a hard glass tube bent to deliver the air just above the surface of the liquid. During the evaporation thus conducted, the temperature of the oven was maintained at a point slightly above 100° , actual ebullition being prevented by the cooling effect of rapid vaporization. When the volume of the solution had been reduced to about one-half, the heating was discontinued, and the retort was cooled in a current of pure air. Methyl red was added to the cool liquid as indicator, showing in general an alkaline reaction; this outcome had been arranged beforehand in weighing the acid, in order to prevent possible loss of bromine during the evaporation.

The next step was the completion of the titration, using a very dilute solution (approximately 0.01 *N*) of hydrobromic acid, which had been prepared by diluting the more concentrated acid and standardized by titration against dilute carbonate-free sodium hydroxide and by precipitating with silver nitrate. This dilute standard solution was weighed in a smaller set of weighing burets, and added drop by drop to the solution in the retort. For this purpose, the platinum cover of the retort had been removed and a glass plate having two small openings put in its place; through one of these openings the tube admitting a rapid stream of pure air was passed, while the other served to admit the tip of the weighing buret. When a distinct acid reaction was attained, the buret was removed; and if the amount added was comparatively large the buret was weighed and emptied. If, however, the amount added was small, the buret was placed in the balance case and removed for a second addition after the carbonic acid formed by the previous addition had been expelled. As with the stronger solution, we found that it was possible, using care not to touch the buret with the hands and allowing but little change in the temperature of the room, to work with the buret for several hours without producing a significant change in the weight.

The expelling of the carbon dioxide produced by the addition of dilute acid was usually complete within one-half hour at a temperature just below boiling, with a rapid current of pure air passing over the solution. In no case was there a change in the depth of indicator color after the solution had been heated for one hour. Consequently, this was the usual time of heating the retort, after the addition of a portion of dilute acid. Experience taught that a certain depth of pink was required in order that the solution would be left neutral when the excess of carbonic acid had been expelled, and this helped materially to shorten the tedious process of reaching the end point by this method. In short, this method of adding successive small portions of very dilute hydrobromic acid was continued until an end point slightly on the acid side of exact neutrality was reached, which remained unchanged when cold, after at least an hour's heating, gently with slight boiling during the last stage. It was thought

for a time in the preliminary work that the end point might be determined in a hot solution; but the action of the indicator is less reliable at the higher temperature under the conditions concerned; and the difficulty of manipulating the hot solution, especially because of the obstruction of clear vision by the drops condensed on the glass plate, caused us to cool the liquid in order to attain the accuracy demanded.

In two titrations an equivalent amount of *p*-nitrophenol was added to the methyl red. This mixture is very well adapted for the titration of all strong acids and bases, working from either acid or alkaline solution. With a concentration of ionized hydrogen of 10^{-8} , the mixture shows a distinct yellow color, at 10^{-7} the color is a very faint greenish yellow, almost colorless, while at 10^{-6} the pink of methyl red appears. In hot solution it is less reliable than methyl red alone, tending to make the solution appear too alkaline; but it resumes its normal reaction when cooled to room temperature. It cannot be depended upon in solutions containing more than 15 or 20% of dissolved substance, especially in sulfate solutions. The weight of the indicator substance required is very small; from 0.05 to 0.08 mg. of methyl red sufficing for 100 cc. solution;—and the amount transformed, when a distinct pink is noticed, is not more than one-half this, as determined by Noyes's method of superimposing solutions. Hence, considering the high molecular weight of the indicator, it is certain that no weighable amount of acid or base was required to combine with the indicator. Confirming this conclusion, it was found that one drop of 0.01 *N* solution of acid containing 0.03 mg. of bromine would change the reaction from distinct alkaline to distinct acid. For yellow or red indicators the eye is much more sensitive to a small change in color when the solution is placed in the bottom of a platinum vessel than when it is contained in glass or porcelain. The methyl red, of course, gives the final evidence as to the true neutral point, but for rapid work the mixture of indicators can be used to advantage, since it gives more warning of approach to the end point from either acid or basic side.

After the sodium carbonate had been neutralized with hydrobromic acid, the sodium bromide solution resulting was quantitatively transferred to a glass-stoppered precipitating flask, and diluted; and the calculated quantity of silver, having been dissolved with great precaution in nitric acid, was added. The exact end point of the precipitation was determined in the usual nephelometric manner.

The above-described method of reaching the end point by gradual addition of very dilute hydrobromic acid was employed in five of the six determinations. In the third experiment (No. 11 in the second table below) a very slight excess of hydrobromic acid was added during the first operation. This excess was titrated very carefully with dilute, carbonate-free sodium hydroxide solution which had been standardized

against both dilute and concentrated hydrobromic acid solutions. The fact that in this experiment essentially the same quantity of hydrobromic acid was used as in the others, suggests that the danger of loss of bromine during evaporation from an acidifying liquid is very slight.

Besides thus finding the weight of silver needed to precipitate the ionized bromine balancing the ionized sodium from the sodium carbonate, we made separate determinations of the amount of silver needed to precipitate given weights of the same solution of hydrobromic acid, and also in four cases weighed the silver bromide which resulted. By giving the exact weights of silver and of bromine corresponding to a given weight of the hydrobromic acid solution, these determinations made it possible to compute (in a way entirely independent of the other determinations) the amount of silver and silver bromide corresponding to given weights of the solution used for neutralizing various portions of sodium carbonate—it being assumed, of course, that the neutralization was correctly performed. The agreement of these results with the others showed that, at least as far as the determination of the bromine was concerned, the earlier results were trustworthy. They showed, moreover, that no significant amount of hydrobromic acid was lost, on the average, during neutralization and evaporation, for the silver analyses were made in one case after evaporation and in the other case without any such treatment. Several of these analyses were made in the midst of the earlier series; indeed, the intention was to make them alternately.

The question having arisen as to the possible action of the dilute hydrobromic acid on the resistant bottle in which it was kept, experiments were instituted on purpose to test this point; for such action would have had a highly deleterious effect upon the result, introducing sodium bromide from a foreign source. The final distillation of the acid had occurred on March 20, 1913, and not long afterwards the solution was made up in its final form. All the analyses were concluded before the 10th of May, an interval of less than seven weeks. Six months after that, the acid having remained in the same bottle, two portions of 60 g. each were separately evaporated in a quartz dish, and the barely visible trace of residue was dissolved in water, transferred to a small platinum crucible, dried and weighed. In each case the residue weighed only 0.1 mg., and the solution in water was found in the nephelometer to contain an amount of soluble bromide equivalent to 0.04 mg. sodium bromide. The amount of sodium bromide formed from the flask during the first six weeks in question must, therefore, have amounted to less than 0.01 mg., a negligible quantity. It should be stated that this flask had previously been used for dilute hydrobromic acid for several years; probably a new bottle would not have yielded so satisfactory a result.

Incidentally, in order to reduce the results to the vacuum standard,

the specific gravity of sodium carbonate was determined by weighing it in a pycnometer, under toluene which had been found in two closely agreeing experiments to have a density at 20° of 0.8661 referred to water at 4°. Thus 9.7256 g. and 5.62691 g. of salt were found to displace 3.32581 g. and 1.92439 g. of toluene, respectively, at the same temperature. The two values for the density of the salt were, therefore, 2.5327 and 2.5325, respectively. This value is distinctly higher than the results of other experimenters. For example, Schroeder found values ranging between 2.43 and 2.51.¹ The difference is doubtless due to the more compact condition of our fused material, and the absence of air held within the pores of the substance.

The first of the tables below reports the weights of silver and silver bromide obtained from given weights of the standard hydrobromic acid solution. All the analyses are recorded, excepting two which met with accidents and could not be brought to completion.

TABLE I.—ANALYSES OF HYDROBROMIC ACID SOLUTION.

No. of expt.	Sample of silver.	Wt. HBr sol (in vac.).	Wt. Ag (in vac.).	Wt. AgBr (in vac.).	Wt Ag per 100.000 g. solution.	Wt. AgBr per 100.000 g. solution.
1.....		205.192	17.05459	...	8.3115
2.....		199.157	16.55319	...	8.3116
3.....	I	212.457	10.14346	17.65772	4.7743	8.3112
4.....	II	211.335	10.08975	17.56405	4.7742	8.3111
6.....	III	201.663	9.62812	4.7744	...
8.....	II	198.356	9.47115	4.7748	...
Average.....					4.77442	8.31135

Thus 100.000 g. of silver bromide are found (from the two averages) to correspond to 57.4446 g. of silver. Baxter² found 57.4453 g.—very nearly the same figure. If we assume Baxter's value (because determined in a simpler way) to be correct, our average, 4.77442 g. of silver, corresponds to 8.31125 g. of silver bromide, or very nearly the result 8.31135 found directly, as given above. The average between these averages, or 8.31130 g. of silver bromide, must represent very nearly the true amount of precipitated halide to be obtained from 100.000 g. of the hydrobromic acid solution. This weight of silver bromide corresponds to 3.5815 g. of hydrobromic acid gas—a figure which gives the percentage composition of the acid, enabling us to know the density of the solution and apply accurately the large correction to the vacuum standard in weighing.

Evidently the concentration of the hydrobromic acid remained essentially constant during the time concerned.

The second table, below, records the weights of hydrobromic acid solution taken for the neutralization of the several samples of sodium car-

¹ Landolt-Börnstein, p. 180 (1912).

² *Proc. Am. Acad.*, 42, 210 (1906).

bonate, the weights of these samples, the weights of the salt corresponding to 100.000 g. of acid solution, and finally the molecular weight of sodium carbonate and the atomic weight of carbon computed from these results (with the help of the weight of silver bromide corresponding to the hydrobromic acid as computed from Table I) if silver is 107.88, bromine 79.916, and sodium 22.995. Incidentally, the total weight of the dilute acid would have been capable of precipitating $1254.946 \times 0.083113 = 104.3023$ g. of silver bromide, hence we may write the proportion:— $104.3023 : 29.43501 = 2 \times 187.796 : 105.995 = \text{Na}_2\text{CO}_3$.

TABLE II.—MOLECULAR WEIGHT OF SODIUM CARBONATE, FIRST METHOD.

No. of expt.	Wt. of HBr sol. (in vac.).	Wt. of Na_2CO_3 (in vac.).	Wt. of Na_2CO_3 per 100.000 g. solution.	Calc. mol. wt. Na_2CO_3 (if AgBr = 187.796).	Calc. at. wt. carbon (if Na = 22.995).
9.....	202.744	4.75555	2.34559	105.998	12.008
10.....	204.673	4.80081	2.34560	105.999	12.009
11.....	208.457	4.88936	2.34550	105.994	12.004
12.....	240.119	5.63157	2.34533	105.987	11.997
13.....	191.646	4.49516	2.34555	105.996	12.006
14.....	207.307	4.86256	2.34559	105.998	12.008
Sum,	1254.946	29.43501	Av., 2.34553	105.995	12.005

The average value for carbon is seen to be 12.005. Considering the circumstances, the agreement of the individual results is as good as could be expected. Before discussing the outcome, another series of more directly obtainable data (namely, the weights of silver actually needed for the precipitation of the exactly neutralized sodium bromide made from these specimens of sodium carbonate) will be recorded. In Table III these several weights of silver are entered in the fifth column (the quality of the silver being indicated by the numerals in the third, which correspond to the various samples already described). The next to the last column, again, contains the computed molecular weight of sodium carbonate, and the last column the atomic weight of carbon, calculated on the same basis as the values recorded in Table II.

TABLE III.—MOLECULAR WEIGHT OF SODIUM CARBONATE, SECOND METHOD.
BY MORE DIRECT REFERENCE TO SILVER.

No. of expt.	Sample of Na_2CO_3 .	Sample Ag.	Wt. of Na_2CO_3 (in vac.).	Wt. of Ag (in vac.).	Mol. wt. Na_2CO_3 if Ag = 107.88.	At. wt. carbon if Na = 22.995.
15.....	(A)	I	4.75555	9.68023	105.995	12.005
16.....	(A)	II	4.80081	9.77222	105.997	12.007
17.....	(B)	II	4.88936	9.95301	105.991	12.001
18.....	(B)	III	5.63157	11.46316	105.998	12.008
19.....	(C)	III	4.49516	9.15003	105.997	12.007
20.....	(C)	II	4.86256	9.89811	105.994	12.004
Sum,			29.43501	59.91676	Av., 105.995	12.005

In brief, it appears that the atomic weight of carbon calculated from the weight of hydrobromic acid taken is exactly identical with that found from the directly determined weight of silver needed to precipitate the acid required for neutralizing the carbonate, each being 12.005 on the basis given, if silver equals 107.88. On the other hand, if $\text{Ag} = 107.871$ (a contingency not impossible), carbon becomes exactly 12.000. The probable error of the average of the entire series of twelve values, if each is given equal weight, is less than 0.001 in the atomic weight of carbon. This is less than 0.003% in the weight of the sodium carbonate, or less than 0.2 mg. in the actual weighing of this salt. The results then are about of the order of accuracy of much of the modern careful work on atomic weights.

The final limits for carbon, *viz.*, 12.000 to 12.005, according to the value for silver chosen, are near that found for carbon in other ways. The range is indeed, as small as the limit of accuracy of the usually accepted data concerning either carbon or silver. That in this entirely different way the old value for carbon should be verified is a highly comforting and reassuring circumstance. It inspires confidence in the accuracy of all the processes concerned, both in the new work on halogen compounds and the older work on carbon; because the single method may be always open to the suspicion that a small constant source of error may have been inadvertently overlooked, the value of such confirmatory evidence is great.

The work could not have been carried out at this time without a generous subsidy from the Carnegie Institution of Washington, which is hereby gratefully acknowledged.

Summary.

A new method of determining the molecular weight of sodium carbonate, and therefore, the atomic weight of carbon, is described, depending upon the neutralization of pure, fused, weighed sodium carbonate by hydrobromic acid, and the precipitation of the bromine both in the resulting sodium bromide and other portions of original solution by means of pure silver. It was found that 29.43501 g. of sodium carbonate were equivalent to 59.91676 g. of silver, and also to a weight of dilute hydrobromic acid which had been found in other tests to be capable of precipitating 104.3023 g. of silver bromide. From these results, if silver equals 107.88, sodium carbonate becomes 105.995 and carbon 12.005, and if silver equals 108.87 and sodium 22.993, carbon becomes 12.000. These limits in both cases are about the possible range of accuracy of the earlier determinations by various methods. Hence the present work, by connecting the various ratios in a new way, shows the consistency of a great variety of earlier work.

THE MOLECULAR WEIGHT OF SODIUM SULFATE AND THE ATOMIC WEIGHT OF SULFUR.

BY THEODORE WILLIAM RICHARDS AND CHARLES R. HOOVER.

Received November 19, 1914.

The preparation and neutralization of pure sodium carbonate, for which the way had been cleared by the work described in the foregoing paper, provides a standard of reference for many other precise determinations. The present paper discusses briefly a series of determinations of the ratio between sodium carbonate thus prepared and sodium sulfate made from it by exact neutralization with sulfuric acid. This comparison had already been attempted long ago by one of the authors.¹ The old determinations were, however, made only as a side issue in the course of an extensive study of the atomic weight of copper; they showed a rather large range of error, and were made with sodium carbonate which was then known to contain traces of silica;² moreover, our recent work on the fusion of sodium carbonate showed that this older specimen, merely dried at a dull red heat, must have contained traces of water also. Therefore, it seemed well worth while to repeat the experiments with modern precision.

The program here was simpler than that involved in the immediately preceding research on carbon. The fused sodium carbonate was carefully weighed, and treated in the platinum retort with a very slight excess of pure sulfuric acid; the solution was then freed from carbon dioxide and evaporated quantitatively in a quartz flask without boiling, but with the help of a current of air; and the remaining salt was fused and weighed.

Preparation of Materials.

Most of the materials were prepared just as before, the same three samples of sodium carbonate being employed. The sulfuric acid was made from the purest acid of commerce (which contained only minute traces of impurity) by three successive distillations in a non-tubulated glass retort over a ring burner. Only the middle portions of each distillate were used. Among other substances sought in this acid was selenium, which was tested for in a 20 cc. portion of the original substance by dilution with twice its volume of water, treatment with half its volume of concentrated hydrochloric acid after cooling and then boiling until the mixture occupied about 35 cc. No free chlorine was detected during this process, and the solution upon treatment with sulfur dioxide showed no red coloration. This test is supposed to show 0.003% of selenium; therefore, presumably, this element was absent. The quantitative outcome to be given later certainly indicates that no element with a greater atomic weight than sulfur was present, confirming the qualitative test.

¹ *Proc. Am. Acad.*, 26, 268 (1891); *Z. anorg. Chem.*, 1, 180 (1892).

² *Ibid.*, 247 and 157, respectively.

The pure redistilled acid was diluted with pure water to a convenient standard concentration, suited to the capacity of the weighing buret and the amount of carbonate to be neutralized.

The preliminary standardization of the standard solution of acid was carried out as follows, much more simply than in the final experiments. This simple preliminary procedure is within the scope of the apparatus in any laboratory, and may be useful to those wishing to standardize an acid solution. A quantity of air-dehydrated, thrice recrystallized sodium carbonate was placed in a weighed platinum crucible. This was heated on a pipe stem triangle while dry carbon dioxide was passed in through a Rose crucible lid, the usual porcelain delivery tube having been replaced by a slightly longer, hard-glass tube. After having been kept at a temperature below fusion for some time, the salt was carefully fused and kept in a liquid condition for a few minutes. It was then cooled in a current of carbon dioxide and weighed again. The crucible and contents were placed in a weighed quantity of the standard solution of sulfuric acid known to be insufficient to neutralize all the carbonate, and the liquid was heated nearly to boiling after the addition of the mixed indicator. When the acid had been exhausted, the effervescence naturally ceased, and the solution of the carbonate proceeded very slowly; therefore, it could be easily determined when more acid was needed. Adding acid drop by drop, from time to time, the carbonate was finally dissolved and the solution remained neutral. The process may, of course, be conducted with even less trouble by adding at first a slight excess of acid and titrating back with hydroxide. By this crude method 1 g. of sodium carbonate was found to be equivalent to 41.032 g. of acid solution, while in the more carefully executed titration in the first regular analysis, 1 g. of pure sodium carbonate was found to be equivalent to 41.0280, or a difference of 1 part in 10,000. This is a degree of accuracy far exceeding that possible by the ordinary methods used for the volumetric neutralization of sodium carbonate, which gives rather questionable results in inexperienced hands.¹ The standard acid evidently contained 2.255% of H_2SO_4 .

An auxiliary solution, 100 times less concentrated, was next prepared by diluting a weighed amount of the main standard solution with a weighed amount of water. These solutions were kept in resistant glass bottles with paraffin-covered rubber stoppers and paraffin-coated syphon tubes. Air was admitted through large U-tubes filled with beads and with portions of solution removed from time to time from the bottles. That a dilute solution may be preserved without appreciable change in concentration, was shown by the results of the titration of hydrobromic acid against sodium carbonate described in the previous paper.

¹ The uncertainty due to the indicator alone may amount to as much as 0.5% in the presence of carbonic acid. See A. A. Noyes, *THIS JOURNAL*, 32, 815 (1910).

The Neutralization and Determination.

The exact titration of accurately weighed amounts of the purest fused carbonate against sulfuric acid was carried out essentially as in the case of the hydrobromic acid. The end point chosen was slightly more on the acid side of exact neutrality, the hydrogen ion concentration being about 10^{-6} , because the excess of acid could be driven off during the subsequent ignition. The non-volatility of sulfuric acid from aqueous solution allowed more variation in the method of reaching the end point than in the earlier case. The quantity of the main sulfuric acid solution required to combine with the observed weight of sodium carbonate was weighed out, and the carbonate was dissolved in the acid in the platinum retort. In determinations 2, 3, and 6 the neutral point was reached by several further very small additions of very dilute acid, as in the earlier case. In Nos. 4 and 5 a slight excess of sulfuric acid was added in the first operation, and the solution was titrated back with standard sodium hydroxide solution from a weighing buret. In No. 1 a very slight excess of acid added was removed by repeated evaporation and ignition of the sodium sulfate to constant weight, followed by thorough fusion in a rapid current of air. These different methods of treatment, by substantially agreeing as to their results, established the fact that the carbon dioxide had been completely expelled from the solution when the end point was reached in the hydrobromic acid analysis described in the preceding paper.

After the solution of sodium sulfate had been rendered neutral or slightly acid, it was concentrated by passing pure air over the solution in the covered platinum retort until the volume indicated that the solution would be slightly more than saturated at room temperature. It was then transferred, while warm, to a small quartz flask in which it was to be evaporated and fused somewhat in the manner employed in a previous research upon silver nitrate.¹ In the present case, however, the flask had the tube for admitting the air fused into the top of the flask, and a side exit tube attached after the fashion of a gas washing bottle. Both tubes were provided with ground quartz stoppers. The flask had a capacity of about 100 cc. and was not too large to weigh accurately. The transference from the retort to this flask was naturally the most delicate part of the work. By placing a curved glass rod within the retort with the curve emerging tangent to the inner edge, but free from the outside portion of the rim, it was possible to pour the solution from the retort along the rod without danger of loss. A small funnel tube drawn out and bent slightly at its extremity guided the stream well down into the inlet tube of the quartz flask, and the transfer was facilitated by clamping the flask in an inclined position. The flask having been filled to within a short distance below the end of

¹ Richards and Forbes, Carnegie Inst. Wash., Publication 69, 51 (1907). *THIS JOURNAL*, 29, 808 (1907).

the inlet tube, was placed in an electric heater, maintained at a temperature just insufficient to cause ebullition—pure air being passed in through a glass tube ground to fit the quartz inlet tube. The retort cover and condenser were then thoroughly rinsed, and the solution with several wash waters placed in the platinum retort and concentrated to small bulk; then the solution was added to the contents of the quartz flask. Generally, three such series of washings were carried out until it was certain that every weighable trace of salt had been transferred. After the sodium sulfate solution had been completely collected in the quartz flask and dried, the large electric oven (which had completely enclosed the flask) was exchanged for another consisting of a fire-clay tube wound for a higher temperature, and large enough to enclose only the bulb. With this heater a temperature just sufficient to fuse the edges of the mass of sulfate was maintained for several hours, after which the temperature was raised for a short time to the point necessary to fuse the salt (about 875°). A current of pure air was passed through the flask throughout all these steps. It was found that two hours' heating at the lower temperature (about 850°) produced constant weight, and that on fusion only a very small apparent loss in weight appeared, the average in five trial determinations being 0.01 mg. per gram of salt. This absence of a decrease in weight shows that very little water was retained within the porous, brittle solid at this high temperature. The final calculation was, of course, made on the basis of the weight of salt after fusion, and for the purpose of correcting this weight to the vacuum standard, the density of fused sodium sulfate (previously unknown) was determined as follows: 6.07615 and 8.43725 g. of salt (*in vacuo*) displaced 1.9519 and 2.7063 g. (*in vacuo*) of toluene, respectively, the toluene having a density of 0.8661 at 20° . The two determinations yielded as results 2.696 and 2.700 for the density, respectively—or in the mean, 2.698.

The weighing of vessels of quartz or glass as large as the flasks and burets used in this work is accompanied always by some difficulty; but if the vessels are provided with precisely similar counterpoises and if each piece of apparatus is kept in a separate desiccator and each weighed under precisely the same conditions after the same time, good results may be obtained. In this work, of course, the weights were carefully standardized, the counterpoises were made of volume and weight like those of the objects to be weighed, the weighing room was carefully guarded as to constancy of temperature, corrections for changes of pressure were applied when needed, and the customary details necessary for accuracy were faithfully heeded. The keeping of the small tube of radioactive material in the balance case greatly helps in the discharge of electrical charges—always so troublesome with large nonconducting vessels. The ideal laboratory conditions possible in the new laboratory, built especially for

this kind of work, greatly facilitated the convenience of the task and accuracy of the outcome. The results of the comparison of sodium carbonate with sodium sulfate are given in Table I. In the first column is given the number of the experiment; in the second, the sample of sodium carbonate; in the third, the weight of sodium carbonate *in vacuo*; in the fourth, the weight of sodium sulfate; in the fifth, the weight of this latter salt corresponding to one gram of sodium carbonate; and in the last column, the atomic weight of sulfur—assuming that the molecular weight of sodium carbonate is 105.995, sodium being 22.995 and carbon 12.005, as found in the preceding investigation. The maximum deviation from the mean is less than 0.003% of the molecular weight of the sodium sulfate, and the "probable error" of the average value is less than 0.001.

TABLE I.—THE RATIO BETWEEN SODIUM CARBONATE AND SODIUM SULFATE.

No. of Expt.	Sample of Na ₂ CO ₃ .	Wt. fused Na ₂ CO ₃ (<i>in vac.</i>). Grams.	Wt. fused Na ₂ SO ₄ (<i>in vac.</i>). Grams.	Wt. of Na ₂ SO ₄ from 1.000,00 g. Na ₂ CO ₃ .	At. wt. sulfur.
1.....	A	5.25191	7.03829	1.34014	32.058
2.....	B	4.50977	6.04382	1.34016	32.060
3.....	B	5.04233	6.75737	1.34013	32.057
4.....	B	3.67340	4.92304	1.34019	32.063
5.....	C	4.18724	5.61151	1.34015	32.059
6.....	C	4.55100	6.09916	1.34018	32.062
Sum,		27.21565	36.47319	Av., 1.340155	32.060

Thus it is clear that 1.00000 part of sodium carbonate is equivalent to 1.340155 parts of sulfate; hence, if silver is taken as 107.88 and sodium carbonate as 105.995, Na₂SO₄ = 142.050 and sulfur is found to be 32.060. This figure is only a little below the value 32.069 found at Harvard eight years ago by a more direct method—the conversion of silver sulfate into the chloride.¹ The substantial agreement of the results affords good evidence that the roundabout comparison adopted in the present research is trustworthy in each of its varied steps, and incidentally confirms the value for carbon given by the foregoing research. Evidently we cannot be far wrong in assuming that the correct value for the atomic weight of sulfur is the mean between the two results—that is to say, 32.065. If silver is taken as 107.871 (instead of 107.88) this value becomes 32.056.

The comparison of the ratio of sodium carbonate to sodium sulfate with the old results of 1891 is not without interest. The average of all the old results² made the ratio 1.0000 : 1.3399, while the average of the last three most trustworthy results made it 1.0000 : 1.3400 (instead of the new value 1.340155). The respective errors of the older averages were thus 0.022 and 0.011%. Errors of this sort are precisely of the order

¹ Richards and Grinnell Jones, *Pub. Carnegie Inst. Washington*, 69, 69 (1907); *THIS JOURNAL*, 28, 826 (1907).

² *Loc. cit.*

caused by the retention of water in the unfused sodium carbonate employed in the early work—and there can be little question that this substance must have really contained in 1891 at least as much water as we found it to contain in 1913, under similar circumstances.¹ The sodium sulfate had been fused, then as now. Hence the atomic weight of copper as found in 1891 by comparison with sodium carbonate must have been lower than the truth by perhaps 0.022. Correcting, we find the recalculated atomic weight of copper to be 63.554 (instead of 63.532²) a value much more nearly agreeing with that found from the direct comparison with silver, namely, 63.57.

This investigation, like the foregoing, was conducted under the favoring auspices of the Carnegie Institution of Washington.

Summary.

The quantitative conversion of pure fused sodium carbonate into pure sodium sulfate is described, the ratio of the equivalent weights of these substances being found to be 1.00000 : 1.340155. Assuming $\text{Na}_2\text{CO}_3 = 105.995$, as found in the preceding research ($\text{Ag} = 107.880$), the molecular weight of sodium sulfate becomes 142.050, and the atomic weight of sulfur becomes 32.060. This is in reasonable agreement with the earlier Harvard value, 32.069, and the mean of the two, 32.065, may perhaps be taken with some confidence as the most trustworthy value thus far recorded. This research, like that immediately preceding it, has been useful in confirming by cross-reference many varied methods and results, and in eliminating slight apparent inconsistencies in earlier results; and the out-come seems to strengthen our confidence in the processes upon which our present table of atomic weights is founded.

A REVISION OF THE ATOMIC WEIGHT OF CADMIUM.

[THIRD PAPER.]

THE ELECTROLYTIC DETERMINATION OF CADMIUM IN CADMIUM CHLORIDE.

BY GREGORY PAUL BAXTER AND MINER LOUIS HARTMANN.

Received November 14, 1914.

In three recent papers dealing with the atomic weight of cadmium, Hulett and his collaborators at Princeton University have obtained concordant results, which indicate that the atomic weight of cadmium

¹ See page 100 of preceding article.

² This recalculation is of the figures on the top of p. 271, *Proc. Am. Acad.*, 26 (1891). Na_2CO_3 is assumed as 105.995 above, instead of as 106.108, as it was twenty years ago.

is 112.3, a value one-tenth of a unit lower than that obtained in the Harvard Chemical Laboratory some years ago. Perdue and Hulett,¹ by the electrolytic determination in a mercury cathode of the cadmium in both the hydrated and anhydrous sulfate, and by the determination of the water in the hydrated sulfate, found the atomic weight of cadmium to be 112.30. Laird and Hulett² simultaneously deposited silver and cadmium electrolytically, the latter in a mercury cathode. From the relation of the weights of the two metals deposited, they compute the atomic weight of cadmium to be 112.31 ($\text{Ag} = 107.88$). Very recently Quinn and Hulett³ have determined by electrolytic deposition in a mercury cathode the cadmium content of anhydrous cadmium chloride and bromide. The atomic weight of cadmium found in this way is 112.3 ($\text{Cl} = 35.458$, $\text{Br} = 79.92$). Thus the three investigations support one another in a striking way.

On the other hand, Baxter and Hines⁴ analyzed anhydrous cadmium chloride, by comparison with pure metallic silver and by weighing the silver chloride formed, with the average result for the atomic weight of cadmium of 112.417, while a little later Baxter, Hines and Frevert⁵ repeated this work on cadmium chloride with the result 112.418. The latter investigators also analyzed anhydrous cadmium bromide in a similar fashion, and obtained the identical value 112.417.

Such a serious discrepancy is very disturbing, since it points to some fundamental difficulty with either the electrolytic determination of metals in a mercury cathode or with the analysis of metallic halides by the "silver" method. In the determination of the cadmium in cadmium chloride, the discrepancy amounts to 0.0004 g. of metal in every gram of chloride, while one gram of cadmium chloride would yield 0.0010 g. less silver chloride if the atomic weight of cadmium has the higher rather than the lower value. Since in all the investigations referred to several grams of material were used in each experiment, the uncertainty is obviously far greater than any ordinary experimental error.

The "silver" method of analysis of metallic halides has already been subjected to prolonged and searching investigation, and has been found to yield results in very satisfactory agreement with those obtained by radically different methods.⁶ Furthermore, in the investigations upon the cadmium halides in this laboratory, no especial difficulties were encountered. The silver halides were found to be free from occluded material, both by direct analysis and by the comparison of the quantity of silver used with

the weight of silver halide produced in each experiment. Furthermore, there was no evidence of basicity in the salts which had been made anhydrous by fusion in an acid atmosphere, and the fact that both chloride and bromide yielded identical results made it improbable that either retained moisture during fusion. We decided, therefore, to repeat a portion of the work of the Princeton investigators, by determining electrolytically the cadmium content of the anhydrous chloride. Neither of the other methods used by Hulett and his collaborators seemed as promising as this one, for, as Richards¹ has already pointed out, hydrated crystals are likely to contain an excess of included or *dissolved* water, while it is not easy to obtain in a coulometer silver deposits in which the proportion of occlusions is known. Both of these difficulties would tend to *lower* the observed atomic weight of cadmium.

The results of this research have been satisfactory beyond our anticipation in the exactness with which they support the earlier Harvard work, for if one adds to the percentage of chloride found by Baxter, Hines and Frevert the percentage of cadmium found here, the sum is exactly one hundred per cent. within the limit of experimental error.

In the analysis of cadmium chloride and bromide, Quinn and Hulett converted weighed amounts of anhydrous salt to sulfate and deposited the cadmium electrolytically in a mercury cathode contained in an amalgamated platinum cup. Our method was simpler and safer, in that the cadmium chloride was not converted to sulfate, but was electrolyzed directly. The greater portion of the chlorine is freed as such at the anode, and, while a small amount of perchloric acid which is formed, remains, this is far less hindrance to the complete deposition of the metal than the relatively large amount of sulfuric acid which results from electrolysis of the sulfate. Even under these conditions small amounts of cadmium invariably remained undeposited, but these were readily collected and determined by evaporation and weighing as sulfate.

Furthermore, our cell was so constructed of glass that it contained the anode as well as the cathode, so that any attacking of the anode by the free chlorine merely resulted in the transfer of platinum from one part of the weighed apparatus to another; and the cell was so nearly closed that explosions of liquid during the drying of the amalgams could cause no loss of mercury.

Contrary to the experience of Quinn and Hulett, we observed no blackening of mercury or electrolyte during electrolysis. This, however, may have been caused by the platinum beaker used by them as cathode.

Purification of Cadmium Chloride.

Although it seemed unlikely that salts of foreign metals in the cadmium material were the cause of the difficulty, yet a large portion of our

¹ THIS JOURNAL, 33, 888 (1911).

energy was spent in the purification of the cadmium. Furthermore, the purity of the different preparations was very carefully followed by photographing the spark spectrum with metallic electrodes in a Féry quartz spectrograph which covered the range 2100–6000 μ . The most difficult impurity to eliminate from cadmium is lead, but we were able to show that no one of our preparations contained a quantity of lead large enough to affect the observed atomic weight of cadmium, and some of the material was wholly free from lead, so far as we could determine.

The spectrographic method of detecting impurities is, of course, a sensitive one. In most cases, extremely small proportions of impurities appear unmistakably in the photograph. For instance, lead analyzed by Mr. F. L. Grover in this laboratory, and found to contain less than 0.004% of copper gave a spectrum in which the two strong copper lines were very prominent, while in the spectrum of one of our samples of crude cadmium, containing 0.2% of lead, the lead line of wave length 4058 was as prominent as many of the strong cadmium lines. None of our material could possibly have contained as much as one-tenth of this quantity, yet 0.02% of lead would raise the apparent atomic weight of cadmium by only 0.01 unit. The difficulty in analyzing material containing only spectroscopic traces of impurities has prevented our finding the limit of sensitiveness of the method in the case of cadmium and lead, but this subject in general is under investigation in this laboratory. We have assumed the complete or almost complete disappearance of the lines of impurities in the spectrum to be an indication that sufficient purity has been attained.

The first specimen of cadmium with which we started was found, spectrographically, to contain about 0.1% lead, a trace of copper, considerable nickel, and traces of thallium, indium and calcium. No zinc lines could be seen in the spectrogram, and subsequent analysis in the wet way confirmed the surprising conclusion that zinc was not present. The purification of this material by electrolysis with a dissolving anode was first attempted. Various electrolytes were tried, the most satisfactory from the standpoint of a compact cadmium deposit being a slightly acid solution of the chloride. If the solution was neutral, basic salts were precipitated. During the electrolysis thallous chloride was gradually deposited on the bottom of the dish. The small crystals of metal which separated were frequently raked toward the platinum cathode by means of a glass rake in order to prevent short-circuiting, but occasionally were removed, and after thorough washing with water centrifugally drained. The crystals were then fused in a thoroughly leached "alundum" boat in a current of electrolytic hydrogen. Electrodes made from this metal gave a spectrum in which only lead and copper lines could be seen in addition to the cadmium spectrum, the lead lines of essentially the original intensity, the copper lines considerably reduced in intensity. Since

a second electrolysis with an electrolyte made from the pure metal produced very little further diminution in the proportions of impurity, the electrolytic method of purification was then discontinued. The crystalline metal from the second electrolysis was washed, dried and fused as before.

Next, the buttons of metal were cleaned by etching with dilute hydrochloric acid and then were dissolved in hydrochloric acid containing a small amount of nitric acid in a quartz flask. Both acids were distilled through quartz condensers previous to use. As soon as the cadmium had dissolved, the solution was evaporated to small bulk four times with a large excess of hydrochloric acid, in order to remove nitric acid, and the salt was twice crystallized from the solution saturated with hydrochloric acid gas, as the acid chloride. The crystals were dried in a vacuum desiccator over caustic soda. This salt was found to contain a small proportion of ammonium chloride, formed presumably by the action of the metal on the nitric acid during solution, but since this ammonium chloride was volatilized during the subsequent fusion of the cadmium chloride, it could do no harm. This specimen of chloride is Sample A.

Since Sample A, after fusion in a current of hydrochloric acid, was found to contain a small amount of black residue, apparently carbon and silica, as will be shown later, the attempt was made to eliminate the difficulty by fusing the salt in a current of hydrochloric acid before crystallization. The mother liquors of Sample A, containing much hydrochloric acid, were used to dissolve more of the twice electrolyzed cadmium, with the help of a small amount of nitric acid, all in a quartz flask. The solution was evaporated to small bulk several times with a large excess of redistilled hydrochloric acid to eliminate the nitric acid. Nearly all the excess of hydrochloric acid was expelled by evaporation in quartz, and then evaporation to dryness in a platinum vessel followed. The dry salt was then fused in platinum boats in a current of hydrochloric acid gas, purified and dried by an apparatus described later, in a quartz tube. When the fused salt was dissolved, a considerable quantity of the black residue was found. This was removed by filtration on a platinum-sponge (Gooch-Munroe-Neubauer) crucible, in such a way that the solution came in contact only with platinum and quartz. The crystals obtained by evaporating the solution in a platinum dish and cooling were crystallized from solution in pure water a second time. This salt is designated Sample B. The yield was small because of the small temperature coefficient of solubility of the chloride.

From the mother liquors of the second crystallization metallic cadmium was obtained by electrolysis between platinum electrodes. Spark electrodes made from this metal by drawing the melted material into hard glass capillaries showed very faintly the lead line 4058, and the copper lines 3247 and 3273, but we estimate the proportions of these impurities

to be certainly less than 0.005%. No platinum lines could be seen.

Sample C was purified first by fractional precipitation of the sulfide with scrubbed hydrogen sulfide gas, as previously done by Baxter and Hines. From a dilute solution of cadmium chloride two small fractions were precipitated and rejected, then nearly all the remainder of the cadmium was precipitated in three fractions. These fractions were thoroughly washed with water, then dissolved in hydrochloric acid and reprecipitated. The first two fractions were combined and dissolved in redistilled sulfuric acid containing enough nitric acid to produce solution, for the red modification of cadmium sulfide formed during the washing of the sulfide does not easily dissolve. The third fraction, the most soluble, was not investigated in this research, since it corresponds to Sample D. The solution of the first two fractions was evaporated in a platinum dish until fumes of sulfuric acid were given off, and allowed to cool. Nearly all the sulfate remained insoluble in the excess of acid. After centrifugal drainage the salt was recrystallized by solution in water and precipitation by the addition of redistilled sulfuric acid, a far more economical and rapid process than crystallization from water. From a water solution of the product, metallic cadmium was deposited electrolytically upon a platinum dish as a loosely coherent mass of crystals, which were leached with water as thoroughly as possible. The greater part of the deposit was dissolved in distilled hydrochloric acid in the platinum dish, and the solution was evaporated to dryness in a quartz dish. In order to precipitate any platinum which might have been dissolved during the solution of the cadmium, a neutral solution of the residue was warmed with a portion of the original electrolytic metal in a platinum dish for some time. After filtration through a Gooch-Munroe-Neubauer crucible, the solution was again evaporated to dryness in a platinum dish and the residue was fused in a current of hydrochloric acid gas, as subsequently described. The fused material was dissolved in water, filtered through platinum sponge, and twice crystallized in platinum. The mother liquor from the first crystallization was tested for sulfate with negative results, showing that if the electrolytic deposit occluded any of the sulfate electrolyte, this must have been removed during the fusion of the chloride in hydrochloric acid. This fusion also served to char any residual organic material and also to separate the greater part of the silicic acid. Metal made from the mother liquors of the final crystals, when examined spectroscopically, showed faint traces of lead, platinum, and copper.

Sample D consisted of material prepared in the earlier researches by Baxter and Hines. Cadmium sulfate which had been made from Sample III (the most soluble) of the sulfide fractionation in the earlier research, was electrolyzed, and the metal converted to chloride exactly as in the case of Sample C. Metal made from the mother liquor of the final cadmium

chloride crystals, when tested spectroscopically, was found to contain the merest traces of copper and platinum. This evidence was very satisfactory in showing that the material used by Baxter, Hines and Frevert was pure.

Samples E and F were purified by crystallization of cadmium bromide. This salt has a much larger temperature coefficient of solubility than either chloride or sulfate, and was found to give a far more rapid and convenient method of purification than any other which we tested. Several hundred grams of crude cadmium containing about 0.2% of lead and traces of copper and thallium, were covered with dilute hydrobromic acid solution and then dissolved by the addition of commercially pure bromine.

A slight excess of bromine was removed by boiling, and the solution was then heated with metallic cadmium for some time to precipitate the more strongly electropositive metals. The solution was evaporated, and the salt content subjected to fractional crystallization according to the diagram shown here. After the first three series of crystallizations the fractions were filtered through platinum sponge, and platinum vessels only were subsequently employed. Metal prepared from the crystals

Fig. 1.

of Fraction 11, so far as could be found out from spectrograms, was free from impurity of any kind.

To prepare Sample E, Fraction 13 was converted to chloride by heating in a current of chlorine, as subsequently described. To prepare Sample F, Fractions 16 and 19 were combined, dissolved in hot water in a quartz flask, and a current of pure chlorine was passed in until all bromine had been expelled. The solution was then evaporated, the salt fused, dissolved, filtered and crystallized as with the other samples. Owing to an accident this material was lost after one analysis had been made.

In the crystallization of the cadmium chloride, owing to the high solubility of the salt, a large proportion of each sample remained in solution in the mother liquors. These were preserved in either quartz or platinum. To prepare Sample G these were combined, evaporated to crystallization,

and the crystal product twice recrystallized. Owing to increased experience in crystallizing cadmium chloride, and to the large amount of available material, these crystallizations were more satisfactory than the earlier ones. This was shown by the fact that metal prepared from the mother liquor of the last crystallization was spectroscopically pure.

Purification of Other Materials.

Water.—All the water was purified by double distillation, first from alkaline permanganate, then from very dilute sulfuric acid. Block-tin condensers were employed, no rubber or cork being used to connect the retort to the condenser. Frequently the water was received in platinum or quartz vessels, otherwise Jena flasks or non-sol bottles were used for storage.

Sulfuric Acid.—This substance was distilled from a non-tubulated glass retort into an air-cooled Jena glass receiver, with rejection of the extreme portions.

Alcohol.—Alcohol was distilled in glass, twice from lime and once from mercury. Fifty cubic centimeters upon evaporation in a quartz crucible left a residue which weighed 0.00016 g. before, 0.00006 g. after gentle ignition. In another experiment 200 cc. of water, 50 cc. of alcohol and 5 cc. of distilled hydrochloric acid were evaporated in a quartz dish, transferred to a platinum crucible and ignited gently with a drop of sulfuric acid. The crucible gained 0.00001 g.

Mercury.—Relatively pure mercury was three times distilled in vacuum.

Preparation of the Cadmium Chloride for Analysis.

The cadmium chloride was dried in preparation for weighing by fusion in a stream of dry hydrochloric acid gas. During this treatment the salt was contained, in the first three analyses, in a platinum boat, but usually in a quartz boat. The boat was placed in a quartz tube, which formed part of a "bottling apparatus,"¹ by means of which the boat could be transferred to the weighing bottle in which it was originally weighed without being exposed to moist air even for an instant.

The hydrochloric acid was generated by the action of the purest commercial concentrated sulfuric acid upon either fuming hydrochloric acid or sodium chloride, and the gas was dried by passing through five towers about 30 cm. long and 4 cm. in diameter, filled with glass beads moistened with concentrated sulfuric acid. Nitrogen was prepared by the Wanklyn method of passing air through concentrated ammonia solution and then over hot copper. The excess of ammonia was removed in two Allihn gas washing bottles containing dilute sulfuric acid, and the nitrogen was purified and dried by passing through towers containing silver nitrate solution, solid potassium hydroxide, concentrated sulfuric acid.

¹ Richards and Parker, *Proc. Amer. Acad.*, 32, 59 (1896); *Z. anorg. Chem.*, 13, 85.

and resublimed phosphorus pentoxide. Air was purified by reagents similar to those used in the purification of the nitrogen. The apparatus for generating and drying the hydrochloric acid was constructed wholly of glass, and the nitrogen and air purifying trains had rubber connections only at the beginning. Preliminary to fusion, the salt was heated gently by means of either an aluminum block furnace or an electric heating coil of "Nichrome" wire until the greater portion of the water had been expelled by efflorescence. The temperature then was raised until the salt was fused, and was maintained at this point for about fifteen minutes in order to insure the expulsion of a possible impurity of either ammonium salt or acids other than hydrochloric. After the salt had been allowed to cool, the hydrochloric acid gas was displaced first by a current of pure dry nitrogen, then by dry air. The boat was next transferred to the weighing bottle inside the "bottling apparatus," the weighing bottle was placed in a desiccator, and, after the desiccator had stood near the balance for at least an hour, the bottle and boat were weighed.

When salt treated as above is dissolved in water, a small amount of black material is left insoluble. Evidence was obtained in the course of this and other work which indicates that this material is largely carbon, but that it may contain silica. The source of the organic matter from which the carbon is produced by charring is not certain. Atmospheric dust and lint are undoubtedly responsible for a portion, the reagents and filters for the remainder. Preparing the hydrochloric acid gas from fused sodium chloride and concentrated sulfuric acid which had been heated with a small amount of permanganate until colorless, produced little or no diminution in the extent of the difficulty, which eliminates the gas in which the salt was fused as the cause. The source of the silica was probably the quartz dishes in which the concentrated solutions were heated.

The proportion of black material can be very much reduced by fusing the salt in hydrochloric acid, dissolving and filtering through a platinum sponge crucible preparatory to crystallization. This was done with all the preparations, except Samples A and E. A very considerable amount of black residue, obtained in purification of one of the samples, gave the evidence concerning the nature of the substance. This was filtered upon a Gooch-Munroe-Neubauer crucible, washed and dried. Upon gentle ignition, the carbon obviously burned, leaving a gray residue which was insoluble in a microcosmic salt bead. Mr. F. L. Grover in an investigation upon lead halides obtained similar evidence.

As has been stated, by suitable purification the proportion of black residue was made very low. In one experiment this was filtered upon a weighed Gooch-Munroe-Neubauer crucible and was found to weigh only 0.00002 g. Mr. Grover has found in lead chloride and bromide, similarly contaminated, in thirty-six experiments on an average 0.004% of black

residue, but the lead salts were not fused prior to crystallization and were to be expected to contain, and apparently did contain, more of the impurity than any cadmium chloride sample, except Sample A which was not fused before crystallization. Evidently, the error produced by the residue at the most could not be large. But in the analysis the difficulty partially took care of itself, for a portion of the residue adhered to the amalgam and was weighed with it, while a portion was evaporated with the washings and upon ignition was burned. Under the circumstances no attempt has been made to correct for whatever slight error may have been introduced.

With Samples E and G, the residue was almost, if not quite, eliminated. Sample E was made from cadmium bromide by heating and eventually fusing in a current of pure dry chlorine containing a small amount of hydrochloric acid gas, the conversion being conducted in the quartz boat in which the salt was finally weighed. The salt was then fused in pure hydrochloric acid gas as described above. Some difficulty was experienced by persistent retention of chlorine gas by the salt even when re-fused in pure hydrochloric acid gas, and, therefore, fusion in the latter atmosphere was prolonged considerably to ensure complete elimination of the chlorine.

Sample G of cadmium chloride also was fused for some time in chlorine before fusion in hydrochloric acid, and no residue could be seen in either the fused salt or its solution.

The chlorine gas in which the salt was fused was generated from manganese dioxide and concentrated hydrochloric acid, and was scrubbed with wet glass wool, charged with hydrochloric acid gas in four towers containing beads moistened with concentrated acid, and dried in four towers of beads wet with concentrated sulfuric acid. The apparatus was constructed wholly of glass.

In the first three analyses a platinum boat was used to contain the salt. In the first analysis it lost 0.00013 g., in the second, 0.00009 g. This is in accord with other experience in the Harvard Laboratory in the fusion of chlorides in platinum boats in a current of hydrochloric acid gas. It is seldom that the loss in weight of the boat is even as large as the above if the acid gas is free from air. On the other hand, if the hydrochloric acid contains air, the platinum may be very seriously attacked. Since this is not at all in accord with the experience of Quinn and Hulett, who report a loss as high as 2.9 mg. in one experiment, one cannot avoid the suspicion that their fusion atmosphere was not free from air. Because of convenience in manipulation rather than for any other reason, in the later analyses quartz boats were used. One of these in nine fusions lost 0.00013 g., while the weighing bottle, which was rinsed in each experiment, and the boat together lost 0.00033 g. Such constancy is all that could be desired. The average weight of the weighing bottle and boat before and after the fusion of the salt was used in the calculations.

The Electrolytic Cell.

In our earlier experiments upon the electrolytic method we attempted to deposit the cadmium and chlorine simultaneously, the former in a mercury cathode, the latter substance upon a silver anode. We met the same difficulty which other experimenters seem to have found in trying to deposit relatively large amounts of halogen in this way, in loosening of the silver halide deposit from the electrode, owing apparently to local complete conversion of the silver to halide.

The problem of disposing of the chlorine otherwise might have been solved as was done by Quinn and Hulett, by converting the chloride to sulfate before electrolysis. Such a step is entirely unnecessary, however, for a platinum electrode of moderate surface is imperceptibly attacked by the evolution of large amounts of chlorine upon it. For instance,

Fig. 2.

Easley¹ in the electrolysis of 125 g. of mercuric chloride found a platinum wire which served as anode to have lost in weight only 0.00015 g. One experiment of our own confirmed this constancy, for a weighed platinum wire anode lost no weight whatever in the electrolysis of several grains of cadmium chloride. Nevertheless, in order to make sure that no difficulty should be met from this source, a cell was constructed of glass with both cathode and anode permanently sealed in place. Thus any metal dissolved by chlorine liberated at the anode would almost immediately be deposited upon the cathode.

In the cell of Form I, in which the first two analyses were carried out, the salt after fusion was dissolved, and the solution was quantitatively transferred to the cell. The closed form was chosen at first in order to facilitate washing the amalgam and to prevent loss of mercury or amalgam by spurting while being dried at reduced pressure. In the later analyses the Form II was employed. The tube of this cell was large enough so that the boat, usually quartz, could be introduced bodily. During electrolysis it was supported upon the anode B, and at the end of the electrolysis it was removed before the amalgam was washed and dried.

The column of bulbs, D, ground into the neck served to catch spray formed during electrolysis. The stopper C was used to prevent loss of mercury by spurting during drying under low pressure, and always was weighed with the cell.

This cell was found particularly satisfactory in every way, and will be used for the exact analysis of other metallic halides in this laboratory.

Method of Analysis.

The cell was carefully washed and provided with a charge of thrice redistilled mercury, which had previously served as cathode during the electrolysis of dilute sulfuric acid for many hours, and was then several times rinsed, at first with water, then with alcohol. The outside also was cleaned with water and alcohol and wiped with a clean lintless cloth. In order to dry the cell and contents it was placed in a tubular desiccator containing fused potassium hydroxide and the pressure was reduced by a mechanical pump to a few millimeters. When the alcohol had evaporated, the cell was transferred to a second vacuum desiccator, containing fresh potassium hydroxide, for two hours. Finally it was placed with its counterpoise in still a third exhausted desiccator with solid potash where it was allowed to stand several hours before being weighed.

When the Cell I was used, the salt contained in the boat was dissolved in the minimum amount of water and the solution was introduced through the central tube. The boat was rinsed and the more concentrated rinsings added to the solution. The more dilute rinsings of the boat, as well as of

¹ THIS JOURNAL, 32, 1123 (1910).

the weighing bottle which originally contained the boat, were evaporated to small bulk in quartz or platinum and added to the main solution. During the electrolysis a slow current of the purest hydrogen was bubbled through the central tube.

When Cell II was used, the quartz boat containing the fused salt was transferred from the weighing bottle to the cell, and the salt was dissolved in the rinsings of the weighing bottle. The column of bulbs was inserted and last of all a small trap at the top of the column of bulbs.

The electrolysis was then started, at first with a current strength of a few tenths of an ampere. Later, when the greater portion of the cadmium was deposited, the current was increased until for the last two hours a potential of about 16 volts was maintained between the electrodes, the current strength being about one ampere. In all, about seven hours were consumed in each experiment. Gases evolved, at the anode at first, later at both electrodes, stirred the solution sufficiently well without other assistance. Toward the end of the electrolysis the column of bulbs was several times rinsed into the cell. In order to prevent heating of the cell, it was kept immersed nearly to the neck in clean, cold water during all of the electrolysis, and during the latter part, when the voltage was high, ice water was used.

At the end of the electrolysis, although practically all the metal was deposited and little chlorine was evolved upon the anode, yet a very considerable residual conductivity persisted with the evolution of hydrogen and oxygen. This was puzzling at first, but the cause was soon found to be the formation of a small amount of perchloric acid during the electrolysis.

When the deposition of the cadmium was essentially complete, *i. e.*, at the end of about seven hours, the cell was rinsed thoroughly with the purest water which had been saturated with the purest electrolytic hydrogen. The rinsing was accomplished by siphoning the liquid from the bottom of the cell into a clean flask and adding water at the top. Needless to say, the voltage between the electrodes was kept at a maximum during this preliminary washing. As soon as the cell was apparently clean, as indicated by a zero reading on the ammeter, it was disconnected from the battery circuit and further rinsed with water, the amalgam being agitated gently to dislodge any liquid which might have been imprisoned between the amalgam and the glass. Then the cell was rinsed with three 5 cc. portions of alcohol. The stopper was now inserted, the outside of the cell was cleansed with water and alcohol and dried with a clean cloth and the cell was placed in a vacuum desiccator. The drying of the amalgam was effected exactly as in the case of the mercury. In almost every experiment the amalgam was bright in appearance.

The aqueous and alcoholic rinsings were combined and evaporated in

a quartz dish over an electric stove. When in small bulk they were transferred to a weighed platinum crucible and after the addition of a drop of redistilled sulfuric acid, they were evaporated to dryness. The residue was ignited to very dull redness and weighed. By precipitation with hydrogen sulfide and colorimetric comparison with standards, this residue was shown to consist chiefly of cadmium sulfate, but it may have contained traces of alkalis and silica extracted from the glass cell. Since, however, the weight of the residue was seldom as much as a milligram, and frequently much less, the assumption that the residue was cadmium sulfate in applying a correction could not have introduced any considerable error. In fact, the agreement of the experiments where the residue was unusually large with those where the residue was small emphasizes the legitimacy of such a correction.

The fact that we were never able to secure complete deposition of the cadmium is interesting in connection with the statement by Quinn and Hulett that no cadmium could be detected in the residual electrolyte of their experiments. They tested for cadmium by means of hydrogen sulfide and say "we evaporated all our electrolytes to one cubic centimeter and tested each in this manner, so there was little chance for any cadmium to escape deposition without being detected." With a four-gram sample of cadmium chloride such as they used, this "one cubic centimeter" would consist mainly of pure sulfuric acid. It is obvious that, unless this sulfuric acid were previously expelled, even large amounts of cadmium might have escaped detection in the residual electrolyte. In order to find out whether complete deposition of the cadmium really can be secured, Mr. M. R. Grose, with a cell like those used in our analyses, electrolyzed about four grams of once recrystallized cadmium sulfate, the current strength at the end being about one ampere, as in Quinn and Hulett's experiments. The electrolyte was carefully removed and evaporated, finally at a temperature sufficiently high to vaporize the sulfuric acid. The residue weighed only 0.7 mg., and while it contained cadmium, was obviously not wholly cadmium sulfate. The experiment was repeated with salt very carefully prepared from the pure bromide and the residue, which in this experiment weighed 0.5 mg., was found to contain about 0.2 mg. of cadmium sulfate. While it is thus unlikely that the error from incomplete deposition of the cadmium was large enough to explain the discrepancy in question, yet it is unfortunate that Quinn and Hulett did not evaporate their electrolytes to dryness in order to make certain that they contained neither cadmium nor any other substance. This is especially so since their cadmium chloride, which was prepared merely by dissolving purified metal, which had been distilled in hard glass, in hydrochloric acid in a Jena flask and evaporating to dryness in a platinum dish, was not subsequently crystallized. It must be said, how-

ever, that Quinn and Hulett, starting with weighed amounts of cadmium, were able to recover essentially all the metal by an electrolytic process similar to the analytical procedure.

In order to find out whether the cadmium amalgam, upon exposure to air, oxidizes continuously, about 75 g. of amalgam were placed in an open platinum crucible and allowed to stand upon the balance pan with occasional weighing. The results were as follows:

Weight after $\frac{1}{2}$ hr.....	104.09162 g.
Weight after $1\frac{1}{2}$ hrs.....	104.09158 g.
Weight after $2\frac{1}{2}$ hrs.....	104.09160 g.
Weight after agitation.....	104.09159 g.

Although the amalgam seemed to be constant in weight, the possibility still existed that a superficial film of oxide formed at the outset might have an appreciable weight. This point was investigated in the following manner:

Several grams of pure cadmium were fused on an alundum boat in a current of the purest hydrogen. The resulting button was perfectly bright and clean. After standing in a desiccator for some hours it was weighed. The counterpoise of one of the cells was provided with about 80 g. of mercury and weighed by substitution for a similar vessel. The button was then introduced and after the cadmium had been allowed to amalgamate with the mercury, the system was weighed. The amalgam was of the same lustrous appearance as those obtained in the analyses.

	Grams.
Weight of vessel + mercury = counterpoise.....	+1.69317
Weight of cadmium.....	3.25227
Sum.....	4.94544
Weight of system after 7 hrs. = counterpoise.....	+4.94555
Weight of system after 31 hrs. = counterpoise.....	+4.94547

If oxidation of the cadmium really occurs, the change in weight is evidently so slight as to be beyond the limit of error of weighing. The lustrous appearance of the amalgams obtained in the electrolyses is further evidence that little oxidation took place.

One experiment was carried out to test the constancy in the weight of the mercury during the washing and drying operations. The cell was prepared for weighing as usual, and weighed. Then it was washed with water and alcohol, dried in vacuum and reweighed. A loss in weight of 0.00007 g. was found.

Further evidence upon this point was obtained by electrolyzing a dilute hydrochloric acid solution in the cell, and after the customary rinsing and drying, determining the change in weight. Furthermore, the rinsings of the cell were evaporated with sulfuric acid in a weighed platinum crucible which was then reweighed. The results follow: The numbers in the col-

umn headed "possible error" are obtained as the algebraic sum of the "change in weight of cell" and "weight of residue" multiplied by 0.54, the proportion of cadmium in cadmium sulfate.

Change in weight of cell. Gram.	Weight of residue. Gram.	Possible error. Gram.
—0.00001	0.00017	+0.00008
—0.00013	0.00012	—0.00007
—0.00004	0.00017	+0.00005

Some of the residue may have been extracted from the column of bulbs used to catch the spray formed in the electrolysis which was not originally weighed with the cell. At all events, since the weight of the residue is divided by two before being applied as a correction, the uncertainty is obviously less than a tenth of a milligram.

For several reasons, error from evaporation of mercury is not to be feared. In the first place, at 20° the vapor pressure of mercury is 0.0013 mm., and the weight of a liter, therefore, 0.000014 g. The desiccators used for the preliminary exhaustion had volumes somewhat less than a liter, the one used for the final exhaustion a volume of about two liters. But since the pressure was not reduced much below a millimeter, practically only the interior of the cells became saturated with mercury vapor. Furthermore, evaporation from the amalgams would be less than from pure mercury. Finally, since the counterpoise was exhausted with the cell at the close, evaporation from it would at least partially compensate for evaporation from the cell. On account of the low vapor pressure of mercury at room temperature, however, the difficulty could not in any case have been serious. Since only about two liters of hydrogen were evolved at the cathode in each experiment, not more than 0.00003 g. could have been lost in this way even if the gas was saturated with mercury.

The weights were standardized to hundredths of a milligram by the substitution method described by Richards.¹ All weighings were made upon a No. 10 Troemner balance. With the heavier objects, such as the weighing bottle, and the cell containing mercury or amalgam, the balance beam was left down some minutes before making observations in order to allow the slight bending of the beam to occur. A small amount of crude radium bromide was kept in the balance case to prevent the objects weighed from retaining electrostatic charges. The weighing bottle and cell were always compared with counterpoises of very nearly the same shape, size and volume in order to avoid variations from changes in atmospheric conditions.

A vacuum correction of +0.000152 g. per gram of cadmium chloride was applied, the densities of the weights and the salt being assumed to be 8.3 and 4.047, respectively. The vacuum correction of cadmium dissolved in mercury was computed as follows:

¹ THIS JOURNAL, 22, 144 (1900).

Temperature.	Density of mercury.	Concentration of amalgam.	Density of amalgam.	Vacuum correction per g. of dissolved cadmium.
20°	13.545	2.97	13.370 ¹	—0.000017
25°	13.534	3.00	13.354 ²	—0.000016
25°	13.534	5.00	13.230 ²	—0.000015

An average vacuum correction of —0.000016 g. was, therefore, applied for every apparent gram of dissolved cadmium.

In a very few analyses the amalgam became so concentrated that a small amount of solid amalgam separated, but not in amount large enough to produce uncertainty in the vacuum correction.

Analyses 1 and 2 in the table of results were made with Cell I, and a platinum boat was employed. In Analysis 3 a cell similar to Cell II was used, but of considerably larger size. A platinum boat was used and introduced into the cell, where it was in contact with the anode during electrolysis, and was finally weighed with the cell. Allowance was then made for the weight of the boat at the outset. In all subsequent analyses a

quartz boat and the final type of cell were employed. In two analyses by mistake the voltage was considerably reduced just previous to the washing, and it was suspected that both cadmium and mercury dissolved by the free chlorine were still contained in the electrolyte. This conjecture was borne out by unusually large residues when the electrolyte was evaporated. Since mercury salts would have been lost by vaporization during the heating of the residue, the final result would be too low. This was apparently the case, the two results being 112.38 and 112.39. Because of the uncertainty and because a third analysis with the same sample of material (Sample D) was subsequently made, the two analyses affected by the accident are not included in the table. In the first analysis in which cadmium chloride which had been fused in chlorine was used, the chlorine was not completely expelled from the salt, as was indicated by a residual brown color. This analysis also yielded a slightly lower result than the average 112.39, and is omitted from the table. All other analyses are included.

It makes little difference how the results are treated. The final verdict is that the atomic weight of cadmium is essentially 112.42 ($Cl = 35.457$; $Ag = 107.880$), an outcome in exact agreement with the earlier work of Baxter, Hines and Frevert.

While the difference between the extremes is nearly 0.1 unit in the atomic weight of cadmium, yet, if the highest result and the lowest result are disregarded the extreme difference is nearly halved. Furthermore, the last five results, obtained with unquestionably the best material and after ample experience had been gained with the method, differ among themselves by only 0.010 unit. All things considered, the average of these last five determinations, 112.417, seems to us to represent most nearly the real verdict of the research.

It is worth noting that the *lowest* result in the table, 112.359, obtained with the smallest amount of chloride used in any of the experiments, is identical with the *highest* result obtained by Quinn and Hulett, 112.36. Furthermore, even without the correction for residue in the electrolyte, the average atomic weight of cadmium from our experiments is 112.39.

The average ratio of cadmium to chlorine obtained in Analyses 14 to 18, 1.58526, corresponds to the percentage 61.319 of cadmium in cadmium chloride, while Baxter, Hines and Frevert found the percentage of chlorine in the salt to be 38.681. The sum of the two is 100.000. So close an agreement is partly fortuitous, for a discrepancy of 0.001% would be extremely difficult to detect by any analytical method yet devised.

Summary.

1. Crystallization of cadmium bromide is found to be a very efficient and rapid method of purifying cadmium material.

2. A modified form of electrolytic cell utilizing a mercury cathode for the direct electrolysis of chloride solutions is described.

3. The percentage of cadmium in anhydrous cadmium chloride is found to be 61.319, while Quinn and Hulett found only 61.298%. The former percentage corresponds to an atomic weight of cadmium of 112.417 ($Cl = 35.457$), a value which is in perfect agreement with the earlier one found by Baxter, Hines and Frevert, 112.418. If chlorine is taken at 35.458, the atomic weight of cadmium becomes 112.421.

The analysis of cadmium bromide by a similar method is now under way in this laboratory, and the results closely confirm the higher value for the atomic weight of cadmium. The method will also be applied to the analysis of other metallic halides.

We are greatly indebted to both the Carnegie Institution of Washington and the Elizabeth Thompson Science Fund for very generous assistance which has enabled us to obtain apparatus best suited for the work.

CAMBRIDGE, MASS.

THE ELECTROLYSIS OF SOLUTIONS OF THE RARE EARTHS.

By L. M. DRNNIS AND B. J. LEMON.

Received November 18, 1914.

Historical.

But little attention appears to have been paid to the possibility of separating the rare earths by electrolysis of aqueous solutions of their salts. Edgar F. Smith¹ stated that "didymium is not precipitated, either as nitrate or acetate, although a partial precipitation takes place at the positive pole." Brauner² electrolyzed a solution of didymium acetate using platinum electrodes. There formed on the negative pole a pale red crystalline crust which contained didymium and acetic acid. Solutions of the nitrate and of the sulfate of didymium gave similar products. Brauner's object in these experiments was to ascertain whether a superoxide would appear on the positive pole. No such formation was noted, and he did not pursue the subject further. In a brief article entitled "Electrolysis of Solutions of the Rare Earths,"³ Krüss makes the following statement: "A solution of a chloride of a rare earth behaves upon electrolysis like a solution of an hydroxide in dilute hydrochloric acid; chlorine and hydrogen are set free at the electrodes, the solution loses more and more hydrochloric acid, and as the amount of the solvent diminishes, the hydroxide of the earth is precipitated in increasing amount. In this manner the rare earths can be removed from chloride solutions of mixtures of the earths, the amounts thus precipitated depending upon the

strength of the current and the duration of the electrolysis. It is to be expected that those bases which are the weakest toward hydrochloric acid will first be precipitated as hydroxides as soon as a part of the hydrochloric acid is decomposed by the electrolysis. 'The stronger bases will remain in solution as the more stable chlorides. In order to remove the hydrochloric acid uniformly from all parts of the solution of the chlorides of the rare earths, electrodes of large surface were employed.' Krüss electrolyzed the solution for ten minutes, and then removed the heavy, dense deposit of hydroxide by filtration. 'The solution was then again electrolyzed for ten minutes, and in this manner small fractions of less than one gram each were obtained. Two electrolyses of solutions of impure yttria were carried out, and determinations of the atomic weights of the earths in the several fractions showed that the method gave quite rapid separation of the different earths. Krüss states at the close of this brief article that electrolysis of solutions of the rare earths might prove suitable for the separation of these elements. It does not appear, however, that he followed the matter further.

Considerable work has been done upon the anodic oxidation of cerium through electrolysis of solutions of cerium salts with platinum electrodes, but inasmuch as this does not concern the direct separation of the earth from solution upon electrolysis, the researches upon this subject will not here be reviewed.

Experimental.

Material.—The material that was employed in the experiments described below consisted of the earths of both the didymium and yttrium groups from which cerium and thorium had been removed. The earths of the didymium group were extracted from the crude double sulfates of potassium and the didymium group, a large amount of this material having kindly been presented to the writers by Dr. H. S. Miner of the Welsbach Light Company. The lanthanum and praseodymium nitrates were prepared from quite pure samples of these two salts that we owe also to the kindness of Dr. Miner. The earths of the yttrium group were obtained from the crude rare earth oxalates from xenotime: the mixture that was used in the experiments showed strong absorption bands of erbium, and rather faint bands of europium, samarium, and holmium. The didymium bands were very faint.

Apparatus.—The first electrolysis was performed in a small crystallizing dish and stationary electrodes of sheet platinum were used. On electrolyzing a slightly acid solution of the nitrates of the didymium group, no precipitate appeared until the free nitric acid had been broken down by the current. As soon as this had been effected, however, a separation of the hydroxides of the earths appeared at the cathode, and the internal resistance of the cell rapidly increased. Upon interrupting the current

and examining the contents of the cell it was found that a portion of the hydroxides had separated in flocculent form resembling aluminum hydroxide, and also that that part of the cathode which was immersed in the solution was heavily covered with a dense, granular precipitate of the hydroxides. It was this coating of the cathode surface that interfered with the passage of the current and caused marked fluctuations in the voltage.

It was thus evident that no definite voltage could be maintained for any considerable length of time unless the cathode surface could be kept free from deposit of the hydroxides. To attain this end, a rotating cathode of copper in the form of a wheel 15 cm. in diameter and 2.5 cm. in thickness was next employed. This was mounted on a horizontal shaft of the same material and was set in such position that the wheel dipped into the solution of the nitrates of the earth to a depth of three centimeters. An anode of platinum was used. A copper scraper was fastened in such position that it rested against the edge of the cathode wheel, and it was hoped that by means of this arrangement the deposit of hydroxides upon the cathode might rapidly be removed, and the voltage in this manner be kept sufficiently constant to permit of fractional decomposition of the different nitrates in solution. The apparatus did not give satisfactory results, and after thorough trial it was abandoned, and a mercury cathode was employed. The mercury was placed in a glass cell about 12 cm. in diameter and 13 cm. high, the layer of mercury being about three centimeters deep. The surface of this mercury cathode was kept clean by violently agitating it by jets of air, the air being conducted into the mercury through a glass tube with three outlets. The anode consisted of a piece of platinum wire 0.76 mm. in diameter. The source of current was a set of eight storage cells, an ammeter and variable resistance were placed in series with the cell, and a voltmeter was connected in shunt with the cell. The aqueous solution of the rare earths that was to be subjected to electrolysis was placed in the cell upon the surface of the mercury.

I. Separation of Lanthanum from the Other Earths of the Didymium Group.

A neutral solution of the nitrates of the rare earths neodymium, praseodymium, lanthanum and samarium, that contained 50 g. of the oxides of the earths in one liter of the solution, was placed upon the mercury cathode in the cell, the mercury was set in agitation by a blast of air, the current was turned on, and the voltage was gradually stepped up to a point where fairly rapid precipitation of the hydroxides took place. The voltage was maintained constant at this value, 9 volts, throughout the series of fractionations, and this voltage was used in the three fractional electrolyses described below. The first fractional electrolysis was of six hours' duration. The current was then turned off, the hydroxides were

allowed to settle, the clear supernatant liquid was siphoned off, and the remaining solution was separated from the precipitate by filtration through a Büchner funnel. The filtrate was then returned to the cell and was again electrolyzed. In this manner eleven fractions were obtained. The hydroxides of each fraction were first thoroughly washed with hot water, were then dissolved in hydrochloric acid, and the small amount of mercury that they were found to contain was removed by double treatment with hydrogen sulfide. The rare earths in the solution were then precipitated from a slightly acid solution with oxalic acid, were thoroughly washed, and were then ignited to the oxides. The atomic weights of the rare earth elements were determined by igniting one portion of the oxalate to oxide and determining the oxalic acid in another portion by titration with potassium permanganate. The details of this run are shown in Table I.

TABLE I.—SEPARATION OF LANTHANUM FROM OTHER EARTHS OF THE DIDYMIUM GROUP.

Number of fraction.	Time in hours.	Color of oxides.	Atomic weights (original material, 140.6).

8.....	5	Color faint	139.6
9.....	3	Color very faint	139.5
10.....	4	White	139.0
Residual solution.....		White	138.9

Plate I.

The absorption spectra of the original solution of Fractions 5 and 8, and of the residual solution were photographed with the aid of a Hilger wavelength spectrometer, Model 1912, with an oxyhydrogen zirconia lamp as the source of illumination. The different solutions used were of the same concentration in respect to the weight of the rare earth oxides contained in a unit volume. For photographs in black and white the Cramer trichromatic plate, which is especially sensitive to the red, was found to give quite satisfactory results (Plate I).

II. Separation of Lanthanum from Praseodymium.

Nineteen and six-tenths grams of fairly pure praseodymium dioxide and 18.9 g. of lanthanum oxide were mixed, dissolved in nitric acid, the solution twice evaporated to dryness, redissolved in water, and diluted to 500 cc. Upon electrolysis of this solution the results shown in Table II were obtained.

The atomic weights of the rare earth elements in these fractions were determined by the method mentioned under I. Inasmuch as praseodymium was present, the active oxygen in the ignited oxide was determined by the Bunsen method and this was deducted from the weight of the oxide

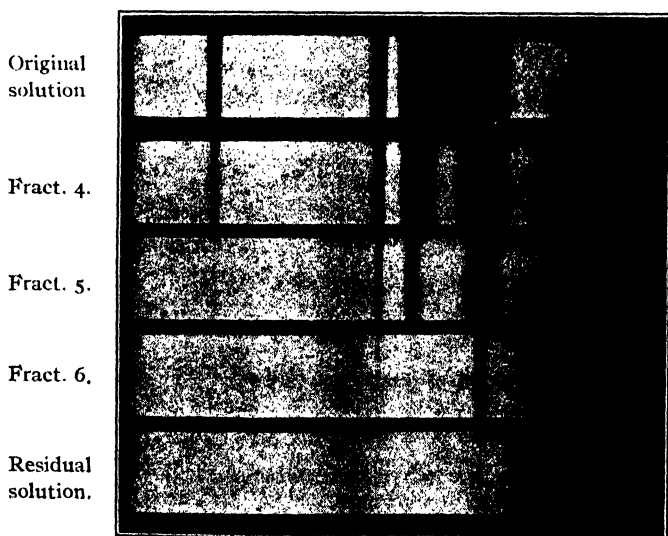

Plate II.

in order to arrive at the amount of Pr_2O_3 that was present. That the atomic weights of the earths in Fractions 1 to 4 inclusive were higher than that of praseodymium is due to the fact that small amounts of other earths of this group were present.

TABLE II.

Number of fraction.	Time in hours.	Color of oxides.	Atomic weights, (original material 141.2).
1.....	9	Black	142.1
2.....	7	Black	141.9
3.....	8	Dark brown	142.0
4.....	9	Brown color fading	141.7
5.....	8	Brown color faint	140.3
6.....	7	Brown color very faint	139.5
Residual solution.....	..	White	138.8

Photographs of the original solution, of Fractions 4, 5 and 6, and of the residual solution are reproduced in Plate II. It will be noted that lanthanum is freed from praseodymium by a very small number of fractional electrolyses.

III. Fractional Electrolysis of the Earths from Xenotime. Separation of Erbium from Yttrium.

Six fractional electrolyses were made with the results as set forth in Table III.

TABLE III.

2.....	8	Light yellow	111.00
3.....	9	Light yellow	109.23
4.....	7	Light yellow	99.73
5.....	8	Faint yellow	93.50
Residual solution.....	..	Very faint yellow	92.08

Original solution.

Fract. 3.

Fract. 4.

Fract. 5.

Residual solution.

* Plate III.

Photographs of the original solution, of Fractions 3, 4 and 5, and of the residual solution are reproduced in Plate III. It will be noted that erbium concentrated chiefly in the first three fractions and that in the succeeding fractions its amount rapidly decreased. The atomic weight of the rare earths in the final fraction, No. 6, was 92, which demonstrates the rapidity of the concentration of yttrium by this method.

The results of the experiments here described upon the fractional electrolysis of different mixtures of the rare earths appear to warrant the statement that the method yields quite rapid separations of some of the rare earths, and that these separations can be effected with far less expenditure of time and labor than by the customary methods of fractional crystallization or fractional precipitation.

VACUUM AND PRESSURE STOPCOCKS.¹

BY MERLE RANDALL AND F. RUSSELL V. BICHOWSKY.

Received November 11, 1914.

The first essential of any stopcock of either hard or soft glass, no matter what its design, is that the glass be perfectly homogeneous and thoroughly annealed, as strains in either the key or frame will in time cause the stopcock either to jam or to leak. Unsymmetrical construction, whether due to poor design or poor workmanship, will, in general, have the same effect. Especially unfortunate is a lack of uniformity in the thickness of the walls of the frame.

Stopcocks of large taper in the key are easier to grind and polish than those of small taper, but are less satisfactory for the reasons that the key must necessarily be shorter, and that the lubricant has a greater tendency to float the key from the seat, especially when the stopcock is used under pressures slightly greater than that of the atmosphere. Careful grinding and very careful polishing are naturally essential.²

Probably the most serious defect of the ordinary straight-bore stopcock is the tendency of the bore to track bubbles and to scrape off the lubricant in its plane and thus allow leakage around the barrel.³ The diagonal-bore stopcock does not allow direct leakage in this way and is, in a measure, self-sealing. It should be pointed out that the key of diagonal-bore stopcocks should be longer than that of straight-bore stopcocks of the

¹ This paper is written in response to several requests for the specifications of the stopcocks in use in this laboratory.

² Morley, *Smithsonian Contributions* No. 980, p. 89 (1895).

³ This scraping and tracking can be partially prevented by proper construction of the apertures of the cross bore and frame.

same diameter, and that the slope of the bore should be sufficient to provide a wide ring of unscrapped lubricant.¹

Diagonal-bore stopcocks, when used with the key in a vertical position in apparatus through which liquids are passed, are likely to trap some liquid in the bore of the stopcock. This is especially inconvenient when mercury is used, as in gas measuring apparatus. It can, however, be entirely prevented by the convenient arrangement of the tubes shown for a two way vacuum stopcock (Fig. 1). The principle is applicable to all other types.

¹ Dr. C. A. Kraus of the Massachusetts Institute of Technology has used a large number of lubricants, and finds that, in general, the stiffer lubricants, such as the gutta percha lubricant recommended by Keyes (*Loc. cit.*), are the more satisfactory. With pressure stopcocks it is necessary to use a very much heavier lubricant than usual. Dr. Kraus has also pointed out a number of desirable features in regard to stopcocks for which we extend our thanks.

² The stopcocks described in Tables I and II are analogous to those shown in Figs. 2 and 3.

Specifications for various convenient sizes of ordinary diagonal-bore stopcocks are given in Tables I and II. Stopcocks made to specification are only slightly more expensive than the stock designs and we have found them much more satisfactory.

Fig. 1.—Self-draining two way vacuum stopcock. Keyes type.

Vacuum Stopcocks.—Of the various types of vacuum stopcocks only that described by Keyes¹ (Figs. 2 and 3) appears to be satisfactory.

Fig. 2.—One way vacuum stopcock. Modified Keyes type.

Fig. 3.—Two way vacuum stopcock. Keyes Type.

¹ Keyes, *Science*, 28, 735 (1902); *THIS JOURNAL*, 31, 1271 (1909).

In this type an extension of the small end of the frame is formed into a closed chamber which can be evacuated at will. Stopcocks having a similarly constructed chamber at the base, but having no means provided for evacuating it, are disadvantageous, as the air in the chamber is under a pressure slightly greater than that of the atmosphere and so tends to loosen the key and leak into the apparatus. Stopcocks of this type, however, can be readily converted into the Keyes type by boring suitable channels. Those stopcocks in which the small end of the barrel is formed into one of the connecting tubes are fairly satisfactory as long as this connecting tube is permanently connected with a vacuum, except that it has the disadvantages of the straight-bore type, is unsymmetrical, and is not as compact as the Keyes form. The cup that is left on the

top of the Keyes stopcock is not intended to be filled with mercury, but is merely to catch the excess lubricant that squeezes out, or it may be filled with a very soft lubricant.¹

Specifications for various sizes of one and two way vacuum stopcocks are given in Tables III and IV.

Pressure Stopcocks.—No glass stopcock suitable for use under pressures has been described.² Professor G. N. Lewis and one of the writers have designed a pressure stopcock in which the taper of the key is reversed in direction and in which the base of the frame has been formed into a deep pressure seat (Fig. 4). This stopcock has been used in a number of investigations in this laboratory and has proven perfectly satisfactory when properly lubricated. The pressure is limited only by the breaking strength of the glass. The deep pressure seat and long handled stem are necessary in order that the stopcock can be properly lubricated.

The frame is first made with an extension M, (Fig. 4) which is afterwards sealed off at N as the last step in the process of assembly. The

Fig. 4.—One way pressure stopcock. Lewis and Randall type.

¹ If it is desired, this cup may be filled with mercury, but it has been the experience of this laboratory that mercury does not increase the efficiency of a well ground and well lubricated stopcock, and is apt to float the key from the seat of one that is poorly made and lubricated.

² Since this paper was written, Professor W. A. Noyes has kindly called our attention to the fact that Dixon and Edgar (*Phil. Trans.*, (A) 205, 169 (1905)) have described a pressure stopcock in which the taper of the key is reversed. This stopcock, in which the pressure chamber is formed into one of the connecting tubes possesses the same disadvantages as the similar vacuum stopcock already discussed.

key of the stopcock is made without the handle below O, but with a long stem on the large end of the key as shown by the dotted lines. By means of this stem the key is then ground into the frame. The extension of the key is cut off at P and the holes are then bored into the key so as to register with the bore of tubes A and B. The handle is then sealed on below O and the base of the barrel sealed off at N. It is usually more convenient to use this stopcock in the inverted position shown in the figure. The stopcock may be made self-draining by inclining the tubes A and B. It has been found convenient to insert a coiled spring between the barrel and the handle in case the stopcock is to be used for vacuum as well as pressure. Satisfactory dimensions are given in Table V.

TABLE V.—ONE WAY PRESSURE STOPCOCK WITH SOLID KEY.

Distance between tubing A and B.....	7.0

Multiple Stopcocks.—The two way stopcock enables one to connect either of two parts of an apparatus separately to a third, but does not allow both to be connected at the same time with the third. Neither does it allow the first two parts to be connected. It is also sometimes desirable to connect more than three parts of an apparatus in various combinations. It is, of course, possible in most cases to accomplish this result by a more or less inconvenient arrangement of a number of one and two way stopcocks. The straight-bore multiple stopcock is unsuitable for careful work, and cannot be used in apparatus under pressure or vacuum.

It is perfectly possible to combine the fundamental principles discussed in the previous sections and make multiple stopcocks of the diagonal-bore ordinary, vacuum or pressure type, as in Fig. 5, which shows a multiple way vacuum stopcock. The essential feature of this design is that the connecting tubes, which may be as many as are desired, are symmetrically placed about the barrel but upon different horizontal planes. The connection, E, to the vacuum seat is bored so that it registers with the lower of the connecting tubes, A, and is at such an angle that none of the other

holes register at the same time. Holes are then bored to a common center from the connecting tubes. The arrangement of these holes may

Fig. 5.—Multiple vacuum stopcock.

be varied to suit the particular purpose of the stopcock. In the stopcock shown, tube A, which is assumed to be connected to the pump may be

separately connected with tube B or C, or B and C may be themselves connected. If, when tubes B and C are connected, a hole is drilled from A to the center, the stopcock will operate as a multiple way stopcock connecting either B or C, or both, to A. The dimensions of this stopcock are given in Table VI.

In conclusion, the authors wish to thank Professor G. N. Lewis and Mr. G. H. Fosdick for their kind suggestions.

BERKELEY, CALIF.

NOTES.

Blast-Lamp for Natural Gas.—The common blast-lamp may be rendered suitable for natural gas by connecting a T-tube to the gas inlet,

so that sufficient air may be introduced with the gas to give a blue flame before blowing air through the regular air nozzle. For thorough mixing of the gases a small mixing chamber is desirable. The illustration shows a lamp so modified, that has been in operation in this laboratory for almost a year, being used by students for

working glass as well as for heating crucibles. Flames of all sizes are secured almost as easily as with coal gas. Copper gauze was placed in the burner tube to prevent "flashing back," but later this precaution was abandoned, as our gas can not be made to "strike back" in any burner. A small thermocouple gave the flame temperatures indicated in the diagram.

JAMES C. McCULLOUGH.

A Modified Kipp Generator.—The diagram, Fig. 1, shows a gas generator which can be used to take the place of a Kipp. Especially adapted to individual student use in qualitative analysis, it ensures a ready supply of hydrogen sulfide gas at any moment.

Three gas bottles (ordinary gas collecting bottles will do just as well) are connected as shown. The reservoir bottle, *a*, which is free to move, contains a three hole stopper. A thistle-tube is inserted in one hole, a bent glass tube extending almost to the top of the bottle in the other hole, while through the third hole is inserted a short piece of glass tubing, *d*. A rubber tube (about 6 mm. bore) has one end attached at *d* and the other to the glass tube at *e* of the bottle *b*. Tube *f* extends almost to the bottom of the bottle *b*, and to the top of the stopper of bottle *c*. The other hole of the generating bottle *c* contains a piece of bent glass tubing closed by a pinch-cock, as shown.

FIG 1

The stopper of bottle *c* is removed, carrying with it the stopper of bottle *b*. Bottle *c* is then filled with the necessary material and the stopper inserted. The other stopper is then inserted in bottle *b*. The clamp is then attached as shown.

The reservoir bottle is filled with the proper strength of acid by means of the thistle-tube. Opening the pinchcock forces acid up into the generating bottle, while closing the pinchcock drives acid automatically back into reservoir bottle. Since the upper end of tube *f* is level with the

FIG 2

FIG 3

stopper, no acid remains in bottle *c*. To empty the generator of spent acid, detach bottle *b*, pour out the contents, replace the bottle and fill again.

Fig. 2 shows another type of reservoir bottle while Fig. 3 shows still another form. The use of gas bottles with openings in them can be substituted.

The unique advantages of this generator are:

1. Slight possibility of large pieces of material getting into the reservoir bottle and rapidly diluting the strength of the acid.
2. Rapid change as a generator for one gas to that of another by adding proper materials.
3. A regulating pressure device by sliding the reservoir bottle up and down the iron rod.
4. And finally, it is quickly constructed, portable, cheap and its capacity can be readily increased.

THEODORE COHEN.

An Improved Heating Apparatus for Maintaining Constant Temperatures in Work with Polarimeters and Refractometers.—In the course of some work upon the effect of temperature upon the specific rotation of optically active substances in solution, it was found necessary to maintain constant temperatures over long periods of time. The conditions demanded that the heating apparatus be one which is simple and convenient and at the same time one which permits the easy reproduction of any given temperature.

Various forms of apparatus devised for this purpose are described in the literature. Some of these consist in principle of a coil for running

water heated either by a Bunsen flame, or an electric coil. Where such methods are used in large crowded chemical laboratories the results obtained are unsatisfactory owing to fluctuations both in the gas and water pressures. Several modifications of this form were tried and discarded. While satisfactory as regards the regulation of temperature, the heating apparatus devised by Landolt for polarimeters is nevertheless inconvenient.

After several attempts the apparatus sketched in the accompanying diagram was perfected and the results obtained far exceeded our expectations.

In the figure, *A* is a round cylindrical vessel 25 cm. in diameter and 40 cm. in depth. Directly in the center and at the bottom of *A* is soldered the small cylinder, *B*, 62 cm. in diameter by 75 cm. in depth. Within the small cylinder rotates a motor-driven stirrer of propeller form. At *C*, slightly below the water level, is soldered a 9 mm. galvanized iron tube. A similar tube opening directly into the center of *B* is soldered to the bottom of the bath. The two open ends, *D*, *E*, are attached directly to the jacketed observation tube by means of short pieces of rubber tubing. Surrounding the bath is a layer, *F*, of felt or asbestos paper.

For temperatures near that of the ordinary laboratory temperature, the bath is heated by means of an immersed incandescent lamp and the temperature electrically controlled by means of a contact toluene regulator in series with a telegraph relay and battery. For temperatures considerably above that of the room, a second lamp is connected in parallel with the first. By applying the heat from a Bunsen burner the bath may be quickly heated and adjusted to any desired higher temperature. Owing to the presence of the small cylinder, *B*, the bath is equally adapted for use with ice at 0°, while for temperatures between 0° and that of the room a cooling coil connected with the water supply may be introduced.

When the bath is connected with the observation tube and the stirrer is driven at the rate of 500 to 600 r. p. m., the water circulates through the tube with an exceedingly high velocity. To judge of the force driving the water, it may be stated that when the tubes, *D*, *E*, are open and the stirrer is revolving at the above rate, the lifting power of the stirrer is sufficient to support a column of water eight inches in height. The speed with which the water is driven under hydrostatic equilibrium is, therefore, obvious. Under these conditions it is possible to maintain any desired temperature constant to $\pm 0.01^\circ$ — $\pm 0.02^\circ$ for any desired period of time.

Owing to the fact that the observation tube is of necessity at some distance from the bath, its temperature will be slightly lower and the difference will be greater, the higher the temperature to which the bath is heated. If the liquid in the observation tube must be at a definite temperature, the temperature of the bath can easily be adjusted so as to

produce the desired temperature and the temperature of the tube regulated with the same degree of constancy.

Measurement of the Vapor Pressures of Solutions.—In the December number of *THIS JOURNAL*¹ there is an article by Frazer and Lovelace on the measurement of vapor pressures of solutions by means of the Rayleigh manometer. A very similar method will be found described by me in *THIS JOURNAL* in 1908,² except that I employed the form of manometer devised by Morley.³ The principle of the two manometers is, however, the same, and the sensitiveness of one can be made fully equal to that of the other.

THE ADDITION COMPOUNDS OF ALDEHYDES AND KETONES WITH ORGANIC ACIDS.

BY JAMES KENDALL AND WILLIS A. GIBBONS.

Received November 14, 1914.

In the first article of this series,⁴ it has been shown that dimethylpyrone forms addition products with organic acids, and that these addition products are uniformly more stable the stronger the acid employed. The basic (unsaturated) properties of dimethylpyrone were regarded as due to the presence of the carbonyl group, $>C = O^+$, the compounds formed being oxonium salts. These views have been more fully developed in subsequent papers,⁵ and found to be consistent with the experimental results throughout.

In the present investigation the same problem is taken up from the reverse direction. The *acid* component of the system is kept constant, while the *basic* component, containing the typical carbonyl group, is made to vary. For the acid component trichloroacetic acid was selected, since in the previous work it has been found, as the strongest of the simple organic acids, to give the most stable compounds with substances containing unsaturated oxygen. For the basic component two substances were chosen as starting points: benzaldehyde, the simplest aromatic aldehyde, and acetophenone, the simplest aromatic ketone.⁶ The examination of the freezing-point curves of these substances with trichloroacetic

⁶ Aliphatic aldehydes and ketones will be studied in a future communication.

acid showed that an equimolecular addition compound was formed in both cases. These compounds differed, however, from those obtained with dimethylpyrone and trichloroacetic acid in being very unstable and largely dissociated into their components on fusion. This was evidenced by the flatness of the maxima on the freezing-point curves.

The effect of the introduction of various groups, of acidic or basic nature, into these simple substances was now investigated. The presence of an *acidic* group in the nucleus should *decrease* the basic characteristics and consequently, according to the theory developed in the preceding articles, diminish the stability of the addition compounds produced, or even prevent the formation of addition products altogether. The effect of a *basic* group, on the other hand, should be to *increase* the tendency towards compound formation, and the isolation of more stable compounds should be expected. These rules were, indeed, found to hold throughout the investigation.

The method followed was substantially the same as has been described in the previous papers, to which reference must be made for the experimental details. The substances employed were, for the most part, Kahlbaum specimens, the purity of which was found to be sufficient for the purposes of the investigation by determination of the point of fusion.¹ In a few cases special methods of purification, however, were adopted.

It has, of course, long been known that aldehydes and ketones form addition compounds of unsable nature with acids, but the investigations previously carried out have always been by the direct organic method—admixture of the components and analysis by combustion of the compound isolated. The freezing-point method has been employed in no single case of the type considered in this paper, except by Maass and McIntosh² for acetone and hydrochloric acid. The advantages of this method are, however, sufficient to recommend its more general adoption. It indicates at once all compounds formed between the two components, analysis is not necessary (since the composition of any addition product is read directly from the curve), and the relative stability of the compounds isolated is also established.

The following aldehydes and ketones were investigated with trichloroacetic acid. (In the case of the aldehydes, the dissociation constants of the corresponding acids³ are appended, to illustrate the acidic or basic character of the substituted group.)

¹ Trichloroacetic acid is extremely hygroscopic, and the last traces of water are removed only by prolonged desiccation over sulfuric acid. The melting points of the samples employed varied from 57.3° to 57.9°.

It may be mentioned here that, in the past, the main investigations upon systems of this type have been in a special field, having as their object the examination of the behavior of α,β -unsaturated ketones with acids. This point will be discussed briefly later, in connection with the results obtained with dibenzalacetone.

The results of the present article are collected in the tables given below; these are arranged as in preceding papers. (T = temperature of *incipient* solidification.) A few typical freezing-point curves are shown in the accompanying diagram.

Aldehydes.

1. Benzaldehyde-Trichloroacetic Acid.—The equimolecular addition product $C_6H_5.CHO, CCl_3.COOH$ was obtained, m. p. 8.4° , stable at its maximum. The compound separates in the form of beautiful colorless needles from a deep orange-pink solution. The system could not be completely investigated, since mixtures containing a large excess of benzaldehyde oxidize rapidly during the course of experiment, and finally deposit crystals of benzoic acid at the low temperatures involved. The freezing points given below were obtained with the use of a freshly-opened "special K" Kahlbaum sample of benzaldehyde, the work being carried through as rapidly as possible.

(a) Solid phase, $CCl_3.COOH$.

% acid.... 100	91.5	83.8	75.2	69.1	63.8
T..... 57.3	51.3	44.7	33.1	21.0	4.3

(b) Solid phase, $C_6H_5.CHO, CCl_3.COOH$.

% acid.... 61.1	55.6	50.0	45.4	40.0	34.3	29.4
T..... 3.6	7.1	8.4	7.2	4.3	-0.8	-6.9

2. Salicylic Aldehyde-Trichloroacetic Acid.—This system also could not be completely investigated, since mixtures containing excess of aldehyde formed, on cooling, a viscous, glassy mass from which no crystallization could be obtained. No compound formation was indicated in the region examined. It is probable that the presence of the hydroxyl group in the ortho position decreases the basic characteristics of the aldehyde sufficiently to prevent combination occurring. (See list, on page 151, of acidic strengths.)

(a) Solid phase, $CCl_3.COOH$.

% acid.... 100	91.8	83.6	74.2	63.4	55.1
T..... 57.9	52.4	44.1	32.2	13.4	-6.9

3. *m*-Hydroxybenzaldehyde-Trichloroacetic Acid. — The hydroxyl group in the meta position is weakly acidic; no compound formation was indicated.

(a) Solid phase, $CCl_3.COOH$.

% acid.... 100	92.7	85.6	79.9	72.7
T..... 57.9	52.6	46.3	39.9	30.3

T..... 24.2	39.3	59.6	75.9	88.9	98.5	107.4

4. *p*-Hydroxybenzaldehyde-Trichloroacetic Acid.—In the *p*-position the hydroxyl group is *basic* in its effect, consequently compound formation should be expected. The components form, on admixture, a delicate pink solution, and the freezing-point curve indicates an equimolecular compound, m. p. 67.8° , stable at its maximum. (See diagram.)

- I. *p*-Oxybenzaldehyde. Subtract 120° from temperature scale.
- II. Anisaldehyde. Subtract 10° from temperature scale.
- III. Vanillin. Subtract 100° from temperature scale.
- IV. Piperonal. Subtract 50° from temperature scale.
- V. Acetophenone. Add 40° to temperature scale.

(a) Solid phase, CCl_3COOH .

% acid....	100	94.0	86.7	79.7

T.....	65.9	79.6	90.9	101.5	109.6	115.6

5. *o*-Nitrobenzaldehyde-Trichloroacetic Acid.—The nitro group increases the acidic strength in all positions. In accordance with this, it was found that the introduction of the nitro group into benzaldehyde deprives it of its basic properties, and no compounds were isolated in any of the three following systems:

(a) Solid phase, CCl_3COOH .

% acid....	100	90.8	82.2	73.3	64.4	55.2
T.....	57.3	52.9	46.5	38.2	27.8	13.5

7. *p*-Nitrobenzaldehyde-Trichloroacetic Acid.(a) Solid phase, CCl_3COOH .

% acid....	100	91.4	84.1	75.7
T.....	57.3	52.2	46.0	37.4

(b) Solid phase, $\text{C}_6\text{H}_4\text{NO}_2\cdot\text{CHO}$.

% acid....	65.5	59.3	52.5	44.6	35.3	21.9	12.2	0
T.....	33.6	46.0	57.3	68.2	78.3	90.7	97.4	104.4

8. Anisaldehyde-Trichloroacetic Acid.—Here the presence of the methoxyl group increases the *basic* characteristics of the aldehyde, and compound formation should be expected. The components give, on admixture, a deep red solution, from which colorless crystals of the addition product $\text{C}_6\text{H}_4\text{OCH}_3\cdot\text{CHO}$, CCl_3COOH are deposited on freezing. The compound is stable at its maximum, and melts at 30.9° . (See diagram.)

(a) Solid phase, CCl_3COOH .

% acid....	100	90.2	80.9	72.8	69.8
T.....	57.9	50.0	37.7	22.2	14.5

(b) Solid phase, $C_6H_4OCH_3.CHO$, $CCl_3.COOH$.

% acid....	69.8	67.6	61.8	55.3	48.7	41.8	35.1	27.1	18.8
T.....	14.5	17.9	24.4	29.4	30.7	27.7	21.9	12.6	0.3

(c) Solid phase, $C_6H_4OCH_3.CHO$.

% acid....	12.0	6.8	0
T.....	-8.1	-4.9	-0.9

9. Vanillin-Trichloroacetic Acid.—In vanillin there has been introduced into the benzaldehyde nucleus a methoxyl group in the *m*-position and a hydroxyl group in the *p*-position; both groups exert a basic influence. The tendency towards compound formation, therefore, should be considerably increased. The components give, on fusion together, a dark red solution, and an examination of the freezing-point curve of the system shows that *three* addition products are formed:

- (1) $C_6H_3OH.OCH_3.CHO$, $2CCl_3.COOH$, stable at its maximum, m. p. 14.3° .
- (2) $C_6H_3OH.OCH_3.CHO$, $CCl_3.COOH$, unstable at its maximum, m. p. 23.0° (by extrapolation).
- (3) $2C_6H_3OH.OCH_3.CHO$, $CCl_3.COOH$, unstable at its maximum, m. p. 45.0° (by extrapolation).

Investigation of the system is rendered difficult by persistent supercooling and by the dark color of the solutions. The freezing-point curve is shown in the annexed diagram.

(a) Solid phase, $CCl_3.COOH$.

% acid....	100	91.4	84.0	77.6	72.3	66.4	65.6
T.....	57.3	51.7	44.5	35.0	25.5	12.0	10.3

(b) Solid phase, $C_6H_3OH.OCH_3.CHO$, $2CCl_3.COOH$.

% acid....	66.0	64.4	62.7
T.....	14.2	13.8	12.8

11. Piperonal-Trichloroacetic Acid.—Here again the introduction of a group of basic nature, $\text{CH}_2 \begin{array}{c} \diagup \text{O} \\ \diagdown \text{O} \end{array}$, into the benzaldehyde nucleus was found

to be accompanied by an increase in the tendency to form addition products with acids. With trichloroacetic acid piperonal forms *two* compounds

(1) $\text{C}_8\text{H}_6\text{O}_3$, $2\text{CCl}_3\text{COOH}$, stable at its maximum, m. p. 37.4° .

(2) $\text{C}_8\text{H}_6\text{O}_3$, CCl_3COOH , stable at its maximum, m. p. 35.0° .

The freezing-point curve of the system is given in the diagram.

(a) Solid phase, CCl_3COOH .

Consideration of Results.

Ten aldehydes and six ketones have been examined with trichloroacetic acid. Five of the aldehydes gave no addition products; from the remaining five systems eight compounds were isolated. These were constituted as follows: (A = aldehyde, B = acid);

(a) 1 of the type A_2B .

(b) 5 of the type AB .

(c) 2 of the type AB_2 .

Of the six ketones, four gave no addition products. From the remaining two systems three compounds were isolated—two of the type AB , one of the type AB_2 . From systems containing an aldehyde (or ketone) and an acid weaker than trichloroacetic, no addition compounds could be obtained.

Compound formation, therefore, is dependent upon the strength of the acid employed—a fact already established in preceding papers. It is also directly dependent upon the acidic or basic nature of the groups included in the aldehyde or ketone. In the former class of substances, benzaldehyde gives a very unstable addition product with trichloroacetic acid. The presence of an *acidic* group in the nucleus causes such a decrease in the tendency towards compound formation that in no single case examined was an addition product obtained. On the other hand,

the presence of a *basic* group increases the tendency towards compound formation, and addition products of a more stable character were isolated.

These rules are not so clearly illustrated by the results obtained with ketones, owing to difficulties in the complete examination of the systems considered. Another regularity, however, is still present here—the color change on admixture of the components is uniformly greater, the more basic the group introduced.¹ Acetophenone, for example, gives with trichloroacetic acid a light yellow solution; phenyl anisyl ketone shows a more pronounced, reddish pink coloration. Similarly, in the case of aldehydes, *o*-nitrobenzaldehyde and trichloroacetic acid form an almost colorless solution, benzaldehyde gives an orange-pink coloration, anisaldehyde a deep red.

This color change has been attributed by Vorländer and Mumme² to a change in the degree of saturation of one or more elements composing the substances present. The variation in the tendency towards compound formation with the acidic and basic strengths of the two components has also been explained, in the preceding papers of this series, on the assumption that the compounds formed are *oxonium salts*. In the systems here investigated, the aldehyde or ketone is to be regarded as the ionizing medium (characteristically unsaturated), and the formation of an equimolecular compound may be expressed as follows:

According to Gomberg and Cone,³ the reaction proceeds quite differently, and the addition compounds formed are *carbonium salts*, *e. g.*:

The arguments in favor of the oxonium structure have already been discussed in full in previous articles, and need only brief recapitulation here. The following points are of importance:

(a) The *instantaneous* nature of the reaction, indicating its *ionic* character. Carbonium salt formation from an aldehyde or ketone cannot be expressed as a simple ionic reaction, but involves also the disruption of the carbonyl linkage. Analogous reactions of this type (*e. g.*, the addition of hydrocyanic acid or alkaline bisulfites) are time reactions.⁴

(b) The regular dependence of compound formation upon the acidic and basic strengths of the two components. This regularity is evident.

¹ Compare Kendall, *THIS JOURNAL*, 36, 1242 (1914).

² *Ber.*, 36, 1470 (1903).

³ Gomberg and Cone, *Ann.*, 376, 183 (1911).

⁴ Stewart, *J. Chem. Soc.*, 87, 185 (1905).

not only in the formation or nonformation of compounds, but also in the relative stability of the addition product obtained. It does not seem probable that the formation of compounds should depend upon acidic and basic strengths unless the reaction were directly ionic.

(c) The isolation of compounds, other than equimolecular, which cannot be represented according to the carbonium hypothesis. Of the twenty-seven compounds listed on page 151, eleven have not the simple equimolecular formula; of the eleven compounds isolated in the present investigation, four are not equimolecular.

In conclusion here, the behavior of α,β -unsaturated ketones with acids may be briefly discussed. Dibenzalacetone, $C_6H_5CH : CH.CO.CH : CH.C_6H_5$ (see 23 and 24 above) has been the subject of frequent investigation in this connection.

Claisen and Ponder¹ first recorded the fact that dibenzalacetone gives an unstable addition product with hydrochloric acid. Baeyer and Villiger,² attempting to determine the constitution of this compound, noted that it was colored intensely red. If addition had taken place through the ethylene bonds, and the compound was a chlorohydrin, then the corresponding dichloride should also be red colored. Examination showed, however, that the dichloride was colorless, consequently the deduction was made that the addition product was an oxonium salt, addition of acid taking place on the carbonyl group.

Baeyer and Villiger assumed that the compound was equimolecular, $C_{17}H_{14}O$, HCl , but Vorländer and Mumme³ found that its composition was $C_{17}H_{14}O$, $2HCl$, and concluded that addition occurred symmetrically on the two ethylene linkages.

Thiele and Straus⁴ showed that the equimolecular compound also existed, but gave it the chlorohydrin structure. Similarly the work of Harries⁵ led to the conclusion that α,β -unsaturated ketones behave *abnormally* with acids, addition taking place by means of the ethylene bonds and not by the carbonyl group. Stobbe,⁶ summarizing the results of these and other previous investigations, has regarded the question of structure as still unsettled.

In the present work two compounds of dibenzalacetone with trichloroacetic acid have been isolated, with the formulae $C_{17}H_{14}O$, $2CCl_3.COOH$ and $C_{17}H_{14}O$, $CCl_3.COOH$, respectively.

The equimolecular compound may be represented either as an oxonium salt or as a chlorohydrin, the carbonium structure is also possible.

¹ Claisen and Ponder, *Ann.*, 223, 142 (1884).

² Baeyer and Villiger, *Ber.*, 34, 2695 (1901).

³ Vorländer and Mumme, *Ibid.*, 36, 2375 (1903).

⁴ Thiele and Straus, *Ibid.*, 36, 2375 (1903).

⁵ Harries, *Ann.*, 330, 185 (1904).

⁶ Stobbe, *Ibid.*, 370, 93 (1909).

To the other compound only the oxonium or the chlorohydrin formula can be given; the former seems to be more probable. It is true that the oxonium structure here involves the assumption of hexavalent oxygen, but that such an assumption is legitimate has already been pointed out from previous results.¹ Throughout the whole of this series of investigations, however, no evidence has been obtained of "unsaturated" substances behaving abnormally in taking up more molecules of acid than "saturated" substances, *i. e.*, no addition of acid to ethylene bonds has been observed.

Summary.

The formation and stability of addition compounds of the types aldehyde—acid and ketone—acid have been investigated. From the twenty-four systems examined, eleven compounds have been isolated.

The results obtained are in complete agreement with the view, developed in previous articles, that the reaction is ionic in its nature and that the compounds formed are oxonium salts.

NICHOLS LABORATORY OF INORGANIC CHEMISTRY,
COLUMBIA UNIVERSITY, NEW YORK CITY.

[CONTRIBUTIONS FROM THE SHEFFIELD CHEMICAL LABORATORY OF YALE UNIVERSITY.]

3-NITRO-4-HYDROXYCINNAMIC ACID AND ITS METHYL ETHER.

By TREAT B. JOHNSON AND EDWARD F. KOHMANN.

Received October 28, 1914.

During the progress of an investigation dealing with the chemistry of nitrated protein, which is now being carried on in this laboratory, it became necessary to obtain for purposes of identification the following two acrylic acids, *viz.*, 3-nitro-4-methoxycinnamic and 3-nitro-4-hydroxycinnamic acids represented by Formulas I and II, respectively.

These two acids have already been described in the literature by Einhorn and Grabfield.² They obtained the acid (I) by application of Perkin's condensation reaction with nitro-anisic aldehyde (III), acetic anhydride and sodium acetate, and assigned to it the m. p. 140°. The corresponding hydroxyacid (II) was prepared by heating this unsaturated acid (I) in an acetic acid solution of hydrobromic acid at 100°. They assigned to this compound a m. p. of 198°.

We have now repeated this work of Einhorn and Grabfield's, and to

¹ Kendall and Carpenter, *Loc. cit.*

² *Ann.*, 243, 362 (1888).

our surprise have obtained two unsaturated acids having entirely different melting points than those given by these investigators. For example, by condensation of nitro-anisic aldehyde with acetic anhydride and sodium acetate, we obtained repeatedly an unsaturated acid corresponding to Formula I, which melted at $247-8^{\circ}$ instead of 140° , as observed by Einhorn and Grabfield.¹ We have also obtained this same acid from other sources,² but in no case have we obtained a lower modification melting at 140° .

When the methoxy acid (I), melting at $247-248^{\circ}$, was heated with hydrobromic acid in acetic acid solution at 100° it easily underwent complete demethylation giving the unsaturated acid (II), melting at 223° . In this experiment also, which was conducted according to Einhorn and Grabfield's directions, we obtained no evidence of the formation of an acid melting at 198° . Both of the two acids (I) and (II) underwent esterification normally, giving their corresponding ethyl esters melting at 100° and $110-111^{\circ}$, respectively. These two compounds were apparently identical with the two esters described by Einhorn and Grabfield.¹

Our acid (I) melting at $247-248^{\circ}$ differed from Einhorn and Grabfield's acid melting at 140° , in its behavior towards bromine. They state that their acid added bromine easily in ether solution, giving the dibromo-acid (IV).

Our compound was far less reactive. In fact, no addition of halogen took place when it was subjected to the conditions of their experiment. On the other hand, it added bromine in cold, glacial acetic acid solution, giving the same dibromo-acid (IV) as was obtained by Einhorn and Grabfield. It melted at $178-9^{\circ}$. It is possible that the differences in m. p. of our acids and those obtained by Einhorn and Grabfield are to be explained by the fact that we are dealing here with a new case of stereo-isomerism. From the available data, however, we are unable to draw this conclusion. We have never obtained evidence thus far of the formation of isomeric modifications.

Experimental.

¹ *Loc. cit.*

² These observations will be described in a future paper by Mr. Kohmann (T. B. J.).

This aromatic aldehyde has been described in the literature. Einhorn and Grabfield¹ prepared it by nitrating anisic aldehyde below 0° with a calculated amount of nitric acid in presence of concentrated sulfuric acid. They found that it melted at 83.5° and established its structure by the observation that a substituted indigo² was not produced by treatment with sodium hydroxide and acetone. Wörner³ later repeated Einhorn and Grabfield's work and obtained what he supposed was a mononitro derivative melting at 72° . This product gave the same hydrazone as Einhorn and Grabfield's aldehyde melting at 83.5° . Wörner did not make an analysis of his nitro derivative and concludes his description of the compound with the following statement: "So bleibt der Widerspruch in den Beobachtungen des Schmelzpunkts von Metanitroanisaldehyd unaufgeklärt." This work was later repeated by Salway⁴ who found that the nitroaldehyde melts at the temperature given by Einhorn and Grabfield.⁵

Einhorn and Grabfield's nitroaldehyde is easily obtained if the experiment is conducted under the following conditions: First, prepare a mixture containing 300 g. of concentrated sulfuric acid and 15 g. of nitric acid (sp. gr. 1.42) and cool to -10° . While holding the temperature of the acid mixture below -10° , then add slowly through a dropping funnel 22.6 g. of anisic aldehyde and then let stand at the same temperature for one hour. On pouring this final solution into one liter of water the aldehyde will separate as a light yellow solid. The yield in one experiment was 18.5 g. and in another 21 g. The compound is easily purified by crystallization from alcohol and melts at 83° .

If the nitration is conducted at a temperature higher than 0° an entirely different result is obtained. Thirty grams of the aldehyde were nitrated with the same proportions of acids but the temperature of reaction was kept between 0° and $+3^{\circ}$. On pouring the resulting mixture into water we obtained a nitroaldehyde melting lower. It was apparently contaminated with an impurity. On repeated recrystallization from alcohol the melting point could not be raised above 73° . A mixture of this product and the pure aldehyde, melting at 83° , melted at $69-80^{\circ}$. This substance was apparently the same product as obtained by Wörner. It seems very probable, from what we were able to observe, that this lower melting substance is simply an inseparable mixture of the mononitroaldehyde (melting at 83°) and the dinitroaldehyde⁶ (melting at 86°). The analytical values obtained support this conclusion (Kjeldahl):

Calc. for $C_9H_7O_4N$: N, 7.73; $C_9H_7O_4N_2$: N, 12.3; found: N, 8.83, 8.87, 8.84.

3-Nitro-4-methoxycinnamic Acid, .—Twenty-one grams
CH:CH.COOH

of mononitro anisic aldehyde were condensed with sodium acetate (12.6 g.) and 29.4 g. of acetic anhydride by heating for 8 hrs. at $140-150^\circ$. After cooling, the resulting mixture was then triturated with dilute aqueous ammonia in order to dissolve the cinnamic acid. On acidifying the alkaline solution with hydrochloric acid the nitro compound separated in the form of yellow crystals. The acid was purified by crystallization from alcohol and separated in long, rectangular prisms or plates, which melted at $247-248^\circ$. The acid crystallized from hot water in the form of needles. It is difficultly soluble in hot water, ether and chloroform. The compound did not respond to Millon's test for a phenolic group. A careful examination of all residues and filtrates failed to reveal the presence of any other acid than this modification melting at $247-248^\circ$. Einhorn and Grabfield¹ have assigned to this compound a m. p. of 140° . The yield of purified acid was 11 g. Nitrogen determination (Kjeldahl):

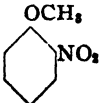

Calc. for $C_{10}H_9O_5N$: N, 6.27; found: N, 6.24.

This same acid was also obtained when the crude nitroanisic aldehyde, melting at 73° (above), was used for the condensation.

3-Nitro-4-hydroxycinnamic Acid, .—Attempts to de-
CH:CH.COOH

methylate the above methoxy derivative by heating with hydrochloric acid were unsuccessful. It was heated in acetic acid, saturated at 0° with hydrochloric acid gas, for 4 hrs. at 100° and at 150° for 2 hrs. without any change. Demethylation was finally effected by heating with an acetic acid solution of hydrobromic acid for 3 hrs. at 100° . After concentrating the acid solution and then pouring into water the hydroxy acid separated. This was purified for analysis by recrystallization from alcohol. It separated in the form of yellow needles which melted at 223° . Einhorn and Grabfield¹ state that this acid melts at 198° . Our product gave Millon's test for the phenolic group. Analysis (Kjeldahl):

Calc. for $C_9H_7O_5N$: N, 6.70; found: N, 6.72.

Ethyl 3-Nitro-4-methoxycinnamate, .—This com-
CH:CH.COOC₂H₅

¹ *Loc. cit.*

pound was obtained by esterification of our methoxy cinnamic acid melting at 247–248°. It was obtained as a crystalline solid melting at 96–98°. It was purified for analysis by crystallization from alcohol and finally separated in large glistening prisms which melted at 99–100°. This same melting point was obtained by Einhorn and Grabfield.¹ The yield of purified ester from 1 g. of the acid was 0.7 g. Analysis (Kjeldahl):

Calc. for $C_{12}H_{13}O_3N$: N, 5.57; found: N, 5.50.

the corresponding cinnamic acid (melting at 223°) by esterification with ethyl alcohol in presence of sulfuric acid. It was purified by crystallization from alcohol and separated in yellow needles which melted at 110–111°. Einhorn and Grabfield found their ester to melt at 108.5°. Analysis (Kjeldahl):

Calc. for $C_{11}H_{11}O_3N$: N, 5.90; found: N, 5.74.

Methyl 3-Nitro-4-hydroxycinnamate.—This new ester is easily prepared by digesting the corresponding acid in methyl alcohol acidified with sulfuric acid. It crystallizes from alcohol in yellow rosetts of fine needles, which melt at 142–144°. The same ester was also obtained by heating the acid in methyl alcohol with an excess of methyl iodide and potassium hydroxide (3 molecular proportions). We obtained no evidence of the formation of methyl 3-nitro-4-methoxycinnamate under these conditions. The ester responded to Millon's test. Analysis (Kjeldahl):

Calc. for $C_{10}H_9O_3N$: N, 6.27; found: N, 6.18.

Einhorn and Grabfield¹ prepared this acid by the addition of bromine, in ether solution, to their 3-nitro-4-methoxycinnamic acid melting at 140°. They write as follows: "— so ist es auffallend, mit welcher Leichtigkeit diese Säure im Stande ist zwei Atome Brom zu fixiren." It has been our experience that our acid melting at 247° adds bromine with difficulty. Attempts to add bromine in ether solution were unsuccessful. The dibrom compound was finally obtained in the following manner: Three grams of the methoxy acid were dissolved in about 250 cc. of glacial acetic acid and the solution cooled to 40°. Two grams of bromine were then added and the solution allowed to stand for 8 days at ordinary temperature. The acetic acid was then removed by distillation in a vacuum at 50° and

¹ Loc. cit.

the addition product dissolved in alcohol and this solution evaporated to remove the alcohol. After this treatment a thick syrup was obtained. This was then dissolved in a little acetic acid and water added when we obtained 2.5 g. of a slightly gummy product, but well crystallized in the form of needles. The substance showed little tendency to crystallize from the ordinary solvents. It was finally obtained pure by dissolving in ether and then precipitating by dilution with petroleum ether. In this manner the acid was finally freed from gum and obtained in a colorless condition. It melted at $178-179^{\circ}$ as observed by Einhorn and Grabfield.¹ Analysis (Kjeldahl):

Calc. for $C_{10}H_9O_6NBr_2$: N, 3.65; found: N, 3.71.

NEW HAVEN, CONN.

ON THE BLUE HYDROCARBON OCCURRING IN SOME ESSENTIAL OILS.

[PRELIMINARY NOTE.]

BY ALFRED E. SHERNDAL.

Received November 7, 1914.

Scattered through the literature of the essential oils are frequent descriptions of blue fractions obtained in the distillation of various oils, the most intensely colored sections distilling between the temperatures, 275° and 300° , or higher. A few oils, such as those of chamomile, wormwood, and cubebs, are notable for their blue or green color before fractionation.

In a few instances where intensely colored fractions have been obtained, the investigators have thought themselves in the possession of a pure substance.² In most cases however, they have recognized that the color is due to the presence of some colored substance other than the bodies making up the bulk of the oil, and the usually accepted view has been, that this is an oxygenated substance related to the sesquiterpene alcohols.³

Semmler⁴ has summarized the literature covering these oils, and remarks that there are two views possible in regard to the blue fractions: either the greater part is colorless, and appears colored owing to the presence of a small amount of an intensely blue substance, or the sections boiling between 275° and 300° , are actually composed principally of a blue compound. That the latter is not the case, however, is evident from a survey of the literature, since the only purification method resorted to is a fractionation out of oils which contain large amounts of sesquiterpenes and sesquiterpene alcohols, with boiling points also ranging from 250°

¹ *Loc. cit.*

² Piesse, "Art of Perfumery," 1879, p. 57.

³ Bartelt, "Die Terpene und Campherarten," 1908, p. 4.

⁴ *Die Aetherischen Öle*, 3, p. 260.

to 300°. For the same reason no importance can be assigned to the various analyses of the blue fractions.

Blue products have also been obtained in the laboratory by various reactions, usually from oils composed principally of sesquiterpenes and sesquiterpene alcohols. In such cases, there seems always to have taken place a dehydration and subsequent oxidation of a sesquiterpene alcohol, or a direct oxidation of a sesquiterpene. For example, Wallach and Tuttle,¹ by the action of phosphoric anhydride, or zinc chloride on guaiol, the alcohol of guaiac-wood oil, obtained a blue sesquiterpene. They considered the color to be due to the presence of a small amount of an oxidation product. On the other hand, Gadamer and Amenomija² obtained a guaiene without blue color, by dehydrating guaiol with potassium acid sulfate.

An interesting observation was made by Hentschel and Wislicenus³ who found, on rectifying the products of the dry distillation of calcium adipate, that the fraction boiling between 135° and 145° at 30 mm., had a blue color resembling that of Roman chamomile.

Semmler and Jakubowicz⁴ obtained blue oils by heating the gurjunene sesquiterpenes in autoclaves filled with air or oxygen.

As far as the writer knows, no connection has as yet been assumed between the blue oils, and the striking color reactions which have frequently been observed when oils consisting largely of sesquiterpenes or sesquiterpene alcohols are treated in dilute solutions with mineral acids. An experiment seems, however, to indicate that such a connection may exist. If oil of gurjun balsam be dissolved in acetic anhydride, and a small amount of sulfuric acid added, the mixture becomes intensely blue, and on diluting with water and distilling the oil in a current of steam, a deep blue distillate is obtained.

Very many oils containing sesquiterpenes and related compounds, give strong color reactions when dissolved in acetic anhydride containing a trace of sulfuric acid. Of the oils examined in this laboratory, those of gurjun, amyris, and guaiac-wood give strong blue or violet colors under these conditions; santal and cedar-wood, none. This test may be used to advantage to detect adulterants in some oils, such as santal.

As to the nature of this blue constituent, nothing whatever has so far been definitely ascertained, for the reason that, as already indicated, it has not been isolated in a state of even approximate purity. A remarkable fact is that a substance with such intense color should possess a comparatively low boiling point, indicating a simple molecule. Semmler⁵ suggests the possibility of a bimolecular structure, closely related to

¹ *Ann.*, 279, 397 (1894).

² *Archiv. der pharm.*, 241, 33 (1903).

³ *Ann.*, 275, 312 (1893).

⁴ *Ber.*, 47, 2252-9 (1914).

⁵ *Aetherischen Öle*, 3, p. 266.

the sesquiterpenes, which on distillation dissociates, and on condensing, again forms a bimolecular compound, with a group similar to that in indigo: $>C : C <$. As a rule, however, the assumption has been made that the blue substance is an oxygenated compound of alcoholic nature.

The following work describes the isolation of this body in a state of purity, as shown by the analysis and reactions. As a pure substance, its remarkable properties become even more striking than before. The analysis shows it to be a highly unsaturated hydrocarbon, but the peculiar grouping of atoms to which it owes its unique properties is more difficult to speculate upon than ever.

The property which was utilized to isolate the substance, and which has heretofore not been noted, is its solubility in mineral acids of certain strengths. The method of preparation was as follows:

Fifty grams of a very blue fraction, freshly steam distilled, were shaken with 10 g. of 63% sulfuric acid, and the mixture allowed to settle over night. The acid layer was then drawn off, diluted with water, and extracted with petroleum benzine until no more blue color was taken up. The benzine solution, dark blue in color, was then shaken out with 85% phosphoric acid until no longer blue, the dark red acid solution drawn off, diluted with water, and extracted with ether. The residue from the evaporation of the ether amounted to 0.141 g., or 0.28%. This, redissolved in 50 g. of a pale yellow oil, gave a mixture with about the same tint as the original, showing that there was no appreciable loss in the preparation.

Larger quantities, isolated in this way, were further purified by distillation with steam, and finally *in vacuo*. The substance thus obtained was a slightly viscid liquid, intensely blue in thin layers, black in quantity, with a weak phenolic odor, suggesting thymol, especially when warm.

Subst., 0.2118 and 0.2294 g. gave CO_2 0.7054 and 0.7587 g.; H_2O , 0.1478 and 0.1903 g.; calc. for $C_{18}H_{18}$: C = 90.84; H = 9.15; found: C = 90.83 and 90.20; H = 9.23 and 9.28.

The molecular weight determination was made by Dr. Earl F. Farnau, of New University, by the cryoscopic method, using benzene as solvent. Found: 187.2 and 193.4 (av., 190.3); calc. for $C_{18}H_{18}$: 198.

The compound is, then, a hydrocarbon, having most probably the formula $C_{18}H_{18}$, and for it the writer would preserve the name "azulene," proposed in 1863 by Piesse,¹ one of the earliest investigators, for the blue fraction which he obtained from oil of worm-wood.

The specific gravity at 25° is 0.9738, when freshly steam-distilled. Exposed to light and air, it is gradually converted into a brown resin. Distilled at atmospheric pressure, the boiling point rises from 295° to 300°, leaving a tarry residue, soluble in ether with a brown color. At about 25 mm. azulene distils from 185° to 195°, leaving a brown residue of about 5%. Since the product had been previously distilled with steam, this

¹ *Compt. rend.*, 57, 1016 (1864).

shows that it cannot be distilled without change under these conditions. When evaporated on the water-bath in an open dish, a brown resin, amounting to 10%, or more, remains.

Azulene is readily soluble in most organic solvents. In 95% alcohol it is miscible in all proportions; in more dilute alcohol the solubility is much less, but even 50% alcohol takes up enough to be tinted, a decided blue.

Its solubility in strong inorganic acids, which makes its isolation possible, is especially remarkable. In 60 to 65% sulfuric acid, azulene dissolves to a clear yellow, strongly fluorescent solution; on dilution with water, it is thrown out again as a blue oil, apparently unchanged. It also dissolves in 50% sulfuric acid, but less readily. The solution in phosphoric acid is remarkable for its fluorescence; reddish yellow by transmitted light, intense apple green by reflected light. These acid solutions can be extracted with benzine without removing any azulene, and by repeating several times, a product can be obtained, free from sesquiterpenes or alcohols.

Azulene is strongly resistant to the action of even strong sulfuric acid. When heated with two parts of 94% acid for fifteen hours on the water-bath, a dark brown solution results, which, on diluting with water, again yields the blue oil. Strong formic acid dissolves it with a green color, but in acetic acid the color remains unchanged, as in the neutral solvents. On mixing dry ether solutions of azulene and hydrochloric acid, no change in color was observed.

Nitric acid in acetic acid solution produces yellow amorphous substances, not further examined.

The oxidation of azulene with permanganate has so far yielded only lower fatty acids.

It is not attacked by sodium in hot alcohol, nor does heating with strong alkali affect the color.

By the action of acetic anhydride and sulfuric acid, a substance was obtained, evidently a sulfonic derivative, which was soluble in water. On adding sodium carbonate in excess a sodium salt separated out, which was recrystallized from hot water. The water solution of the salt is colored violet, and changes to a light green on acidifying. If then shaken with ether, the latter becomes violet, and this color is again taken out by shaking with alkali.

The sodium salt, on heating, gives off blue fumes which condense to a blue oil; at the same time sulfur dioxide is liberated.

On standing three months in a corked bottle, a preparation of the sodium salt had decomposed into a mixture of oil and resin.

The water solution gives blue precipitates with barium and calcium solutions, and is decolorized by bromine water.

It appears established that azulene is closely related to the sesquiterpenes. From no other class of compounds have hydrocarbons been obtained which show such intense color. Colored hydrocarbons which have so far been prepared, are characterized by complex structure or a dense arrangement of the atoms, the intensity of the color increasing with the size of the molecule; for example:

Rubicen, a red hydrocarbon, $\text{C}_{26}\text{H}_{14}$, m. p. 306° .³

It is obvious that in azulene we have an entirely different and unique chemical compound. We hope, in a subsequent communication, to collect further data on this interesting substance.

The writer wishes here to acknowledge his indebtedness to Dr. Francis D. Dodge for helpful suggestions as well as for aid in obtaining material used in connection with the above work.

RESEARCHES ON HYDANTOINS. XXIX. GEOMETRICAL ISOMERISM IN THE HYDANTOIN SERIES.

By TREAT B. JOHNSON AND SIDNEY E. HADLEY.

Received November 19, 1914.

In order that geometrical isomerism may be shown in an unsaturated carbon compound, two fundamental conditions must be fulfilled: first, that the molecule contains a double bond between two of its carbon atoms, and second, that the two radicals linked to each of these two carbon atoms must be different. Theoretically, the accepted structural formula of an *aldehyde-hydantoin* condensation product (I) fulfills both these conditions and consequently a hydantoin of this type might be expected to occur in *cis*- and *trans*-modifications. The constitutions of such isomeric forms might be expressed by the two graphic Formulas II and III, respectively. Several unsaturated compounds of this type (I) have been prepared in this laboratory, but hitherto we have not detected the occurrence of more than one modification. In this paper we will now discuss the first case of this type of isomerism so far observed in the hydantoin series.

(I)

(II)

(III)

1,3-Diphenyl-2-thiohydantoin (VI), which was first synthesized in this laboratory by Wheeler and Brautlecht,¹ condenses with benzaldehyde and anisic aldehyde forming the corresponding condensation products represented by Formulas IV and V, respectively. The benzal com-

(IV)

(V)

ound (IV), which is the only one of the two hydantoin of any interest in this investigation, was found by Wheeler and Brautlecht to melt at 194°. Having occasion to prepare this hydantoin we found, to our surprise, on repeating this experiment, that the hydantoin (m. p. 194°) described by Wheeler and Brautlecht² is not the only product of this reaction. In fact we were able to isolate an isomeric product which melted several degrees lower than Wheeler and Brautlecht's hydantoin. This modification, however, was formed in such small quantities and possessed such unfavorable properties that we were unable to establish conclusively its constitution by chemical means. The structure of the modification melting at 197° was proved by the fact that it underwent reduction with hydriodic acid giving the hydantoin (IX) previously described by Johnson and Shepard.³

Notwithstanding the fact that the hydantoin (IV), melting at 197°, is a stable and definite compound, it undergoes a remarkable change when it is desulfurized by digestion with chloroacetic acid. It combines with this halogen acid, giving apparently an addition product, which can easily be broken down by acid hydrolysis forming smoothly two well defined isomeric hydantoin. We have now concluded that these are geometrical isomers of 1,3-diphenyl-4-benzalhydantoin whose structures may be represented by Formulas VII and VIII. They melt at 192° and 152°, respectively. The higher melting modification, which we have represented as the *trans*-form, is the chief product of the reaction. The lower melting form, or *cis*-modification, is not formed in large amount

¹ *Am. Chem. Jour.*, 45, 446 (1911).

² The true melting point of this hydantoin is 197°.

³ *THIS JOURNAL*, 36, 1735 (1914).

and is characterized by its greater solubility. That this interesting case of hydantoin isomerism is to be explained by the presence of the double bond in the unsaturated molecule is established by the fact that both modifications (VII and VIII) undergo reduction smoothly with hydriodic acid, giving the same saturated compound—1,3-diphenyl-4-benzylhydantoin represented by Formula XI. This hydantoin has previously been described by Johnson and Shepard.¹

We have now made the interesting observation that these same two isomeric modifications of 1,3-diphenyl-4-benzalhydantoin are also formed by condensation of 1,3-diphenylhydantoin² (X) with benzaldehyde. Wheeler and Hoffmann³ state that this hydantoin does not condense with anisic aldehyde when heated with it in the presence of sodium acetate, acetic acid and acetic anhydride. With benzaldehyde the condensation can easily be brought about with smooth formation of hydantoin. The *trans*-modification, however, is the chief product of the reaction. Both forms were isolated and their identity with the two hydantoin obtained by desulfurization of 1,3-diphenyl-4-benzalthiohydantoin completely established.

These various transformations are expressed by the following formulas:

¹ *Loc. cit.*

² Bischoff and Häusdörfer, *Ber.*, 25, 2274 (1892).

³ *Am. Chem. J.*, 45, 368 (1911).

Experimental Part.

1,3-Diphenylthiohydantoin (VI).—This hydantoin, which served as the starting point in our investigation, was prepared according to the directions of Wheeler and Brautlecht¹ by heating ethyl anilinoacetate with phenylisothiocyanate. While this compound is easily obtained in quantity by this method, we have observed, however, that it is not the only product of the reaction. In several cases we have obtained a secondary product which melts several degrees higher than the diphenylthiohydantoin (212°). Whether we are dealing here with an unique case of isomerism or polymerization will be decided by a further investigation.

1,3-Diphenylhydantoin (X).—This hydantoin² is easily obtained by desulfurization of 1,3-diphenylthiohydantoin. This was accomplished by digestion of the thiohydantoin with chloroacetic acid. Fifteen grams of the thiohydantoin and 150 g. of chloroacetic acid were digested with 50 cc. of water, on a sand bath, for 9 hrs. The mixture was then diluted with water, when a gummy product was obtained. This was separated from the water solution and finally heated with boiling hydrochloric acid when thioglycollic acid and diphenylhydantoin were formed. The latter was purified by recrystallization from alcohol and melted at 139°. The yield of purified material was 10.5 g.

1,3-Diphenyl-4-benzal-2-thiohydantoin (IV).—Wheeler and Brautlecht¹ first prepared this compound by condensing benzaldehyde with 1,3-diphenylthiohydantoin and found it to melt at 194°. We now find on repeating this experiment that this hydantoin is not the only product of this reaction. While this hydantoin, which we found to melt at 197°, is the chief product formed we have observed that it is accompanied by two other substances of characteristic properties. One of these is apparently a stereoisomeric modification of the hydantoin (melting at 197°) and the other is apparently identical with the substance of unknown constitution, which is formed by heating phenylisothiocyanate with ethyl-anilinoacetate.

The condensations were generally carried out in the following manner: Forty-seven grams of the diphenylthiohydantoin, 40 g. of benzaldehyde and 76 g. of anhydrous sodium acetate are dissolved in 245 cc. of hot glacial acetic acid and the solution heated in an oil bath at 150° for 12–14 hrs. The acid solution is then diluted copiously with cold water and cooled, when the crude hydantoin separates in a granular condition. The yield of crude material varies somewhat but generally is between 90–98% of the theoretical. On digesting this crude product with glacial acetic acid, all dissolves with the exception of a small amount of yellow material which generally melts above 280°. On cooling the acetic acid solution

¹ *Loc. cit.*

² Bischoff and Häusdörfer, *Loc. cit.*

the diphenylbenzalhydantoin separates at once and is easily obtained in a pure condition (m. p. 197°) by recrystallization from acetic acid. After separation of the diphenylbenzalhydantoin a dark red acetic acid filtrate is always obtained, which contains apparently a small amount of a substance isomeric with the hydantoin melting at 197° . This can be isolated in an impure condition by evaporating the acetic acid filtrate at 100° to remove acetic acid and then triturating the gummy residue with hot alcohol. The coloring material and isomer are removed by this treatment, leaving behind the 1,3-diphenyl-4-benzalthiohydantoin. On cooling the alcoholic solution the isomer separates as a red powder having no definite melting or decomposition point. It was not present in large amount. A nitrogen determination gave (Kjeldahl):

Calc. for $C_{22}H_{16}ON_2S$: N = 7.8; found: N = 7.36.

In another experiment when we used 10 g. of the thiohydantoin, 15 g. of sodium acetate, 11 g. of benzaldehyde and 50 cc. of glacial acetic acid, we obtained 13 g. of the hydantoin melting at $196-197^{\circ}$. This yield was nearly the theoretical amount.

1,3-Diphenyl-4-benzyl-2-thiohydantoin (IX).—This hydantoin has been described in a previous paper by Johnson and Shepard.¹ We now find that the same compound is also formed by reduction of the above benzalthiohydantoin with hydriodic acid in the presence of phosphorus. This was accomplished by digesting the hydantoin with the halogen acid and phosphorus in acetic acid solution. The hydantoin was purified by crystallization from alcohol. It separated in rosetts of needles which melted at 130° . Analysis (Kjeldahl):

Calc. for $C_{22}H_{18}ON_2S$: N = 7.8; found: N = 7.53.

dantoin is easily obtained by desulfurization of the corresponding 2-thiohydantoin. Three grams of the thiohydantoin (melting at 197°) and 30 g. of chloroacetic acid were digested for 2 hrs. A clear solution was obtained. This was then diluted with water when a light yellow, gummy product separated. After separation from the water this substance was then boiled with strong hydrochloric acid when it was completely changed into the above hydantoin. The yield of crude material was 2.7 g. The hydantoin was purified by crystallization from glacial acetic acid. It separated from this solvent, on cooling, in light yellow prisms with tetrahedral form and melted at 192° . They did not respond to a test for sulfur. Nitrogen determination (Kjeldahl):

Calc. for $C_{22}H_{16}O_2N_2$: N = 8.22; found: N = 8.39, 8.11.

¹ *Loc. cit.*

(*cis*)-1,3-Diphenylbenzalhydantoin.—In another experiment we used the following proportions: 14 g. of diphenylbenzalthiohydantoin, 140 g. of chloroacetic acid and 47 cc. of water. These were heated for 5 hrs. when a similar result was obtained as in the previous experiment. The gummy product was decomposed in the usual manner by digesting with hydrochloric acid and the resulting crude hydantoin then purified by crystallization from acetic acid. The hydantoin melting at 192° was obtained as before. After separation of this substance the acetic acid filtrate was then concentrated and cooled, when we obtained a crystalline substance which melted at $145\text{--}152^{\circ}$. This was identified as an *isomer* of 1,3-diphenyl-4-benzalhydantoin. It was purified by crystallization from glacial acetic acid and separated in rosetts of prisms which melted sharply at $150\text{--}152^{\circ}$. It did not rearrange into the *trans*-modification when heated at 192° . The yield of purified material was 1 g. Analysis (Kjeldahl):

Calc. for $\text{C}_{22}\text{H}_{16}\text{O}_2\text{N}_2$: N = 8.22; found: N = 8.03.

In a third experiment we obtained, after desulfurization of 15 g. of 1,3-diphenyl-4-benzal-2-thiohydantoin, 10.5 g. of the *trans*-hydantoin melting at 192° and 1.5 g. of the *cis*-modification melting at 152° .

The Condensation of Benzaldehyde with 1,3-Diphenylhydantoin.—1,3-Diphenylhydantoin undergoes condensation with benzaldehyde giving *cis*- and *trans*-1,3-diphenyl-4-benzalhydantoins. The yield, however, of the *cis*-modification is very small. In our first experiment the condensation was effected by digesting 5 g. of the diphenylhydantoin and 3 g. of benzaldehyde with 15 g. of sodium acetate, 10 cc. of acetic anhydride and 20 cc. of glacial acetic acid for 4 hrs. at 150° . On cooling the resulting solution and then diluting with water the hydantoin separated. This was purified by recrystallization from acetic acid and melted at 192° . This same result was also obtained when the condensation was effected in the presence of potassium acetate. In neither of these experiments did we detect the presence of any *cis*-diphenyl-4-benzalhydantoin melting at 152° . It was only by working with larger quantities of material that we were finally able to isolate the *cis*-modification. In a third experiment 47 g. of the diphenylhydantoin were condensed with benzaldehyde according to the described conditions. After pouring the reaction mixture into water, to separate the crude hydantoin, and then crystallizing from acetic acid, we obtained 28 g. of the *trans*-hydantoin, melting at 192° . The acetic acid filtrates were then combined and evaporated at 100° to remove the excess of acetic acid when we obtained a dark red, gummy residue. This product was triturated with warm 95% alcohol and the mixture allowed to stand for several hours, when we finally obtained about 5–6 g. of a semisolid substance insoluble in the alcohol. This was separated from adhering oil by filtering and purified by recrystallization from acetic

acid. After the first crystallization this melted at $130-150^{\circ}$, indicating a mixture of the two isomeric hydantoins. Separation was finally effected by fractional crystallization from acetic acid. The *cis*-modification is more soluble in this solvent than the *trans*-form and in this case sufficient material was available to enable us to isolate the *cis*-modification. It crystallized from acetic acid in needles which melted at the same temperature as the hydantoin obtained by desulfurization of the corresponding 2-thiohydantoin. A mixture of the two substances melted at $150-2^{\circ}$.

Reduction of *cis*- and *trans*-1,3-Diphenyl-4-benzalhydantoin.

1,3-Diphenyl-4-benzylhydantoin (XI).—This hydantoin, which has been described in a previous paper by Johnson and Shepard,¹ is formed when the *cis*- and *trans*-modifications of 1,3-diphenyl-4-benzalhydantoin are reduced with hydriodic acid. This was accomplished by digesting the unsaturated hydantoins in glacial acetic acid with hydriodic acid and in presence of a little red phosphorus. After the reduction was complete the solution was then diluted with water when the hydantoin separated as a gum. In some experiments the excess of acetic acid was first removed by evaporation at 100° , but under both conditions the same gum was obtained. This was purified by dissolving in ether, washing with a little bisulfite solution to remove a trace of iodine and then drying the ether solution over anhydrous calcium chloride. On allowing the ether to evaporate the hydantoin was finally obtained in a crystalline condition melting at $58-62^{\circ}$. The compound is very hygroscopic. It is extremely soluble in cold alcohol, ether, benzene acetic acid, acetone, chloroform, ethyl-acetate and ligroin but practically insoluble in water. It does not dissolve in cold sodium hydroxide solution. The compound agreed in all its properties with Johnson and Shepard's 1,3-diphenyl-4-benzylhydantoin.

NEW HAVEN, CONN.

RESEARCHES ON PYRIMIDINES. LXXIII. ALKYLATION OF 2-MERCAPTOPYRIMIDINES.

By TREAT B. JOHNSON AND HOWARD W. HAGGARD.

Received November 23, 1914.

The papers so far published from this laboratory on the alkylation of 2-mercapto-6-oxypyrimidines have been confined to a description of results obtained from the study of mercapto compounds in which the mercapto grouping contained a saturated alkyl radical, *viz.*, CH_3 -, C_2H_5 -, $\text{C}_6\text{H}_5\text{CH}_2$ -, etc. In all of the cases examined, with one exception, mercapto groups of this type have favored substitution in the 1- and 3-positions of the pyrimidine ring. With these results at hand it then became

¹ *Loc. cit.*

of interest to determine what influence, if any, negative mercapto groupings would have on the formation of alkylation products. In other words, would such combinations be favorable to select for the preparation of 3-alkyl derivatives? In order to acquire further data on this interesting question¹ we selected for study a mercaptopyrimidine containing an unsaturated allyl group in the 2-position, *viz.*, 2-allylmercapto-4-methyl-6-oxypyrimidine (I). The results of this investigation are now presented in this paper.

2-Allylmercapto-4-methyl-6-oxypyrimidine (I) was prepared by the action of allylbromide or iodide on the sodium salt of 2-thio-4-methyluracil (V). At the beginning of our work we first compared the behavior of this new mercaptopyrimidine (I) with that of 2-methylmercapto-4-methyl-6-oxypyrimidine (II)² towards methyl iodide and allylbromide, respectively, in order to find out whether both reactions would lead to the formation of isomeric nitrogen-substitution products. To our surprise they underwent alkylation in an entirely different manner. The sodium salt of the allylmercaptopyrimidine (I) interacted with methyl iodide giving smoothly 2-allylmercapto-1,4-dimethyl-6-oxypyrimidine represented by Formula VIII. We obtained no evidence of the formation of a 3-methylated derivative. On the other hand, the sodium salt of 2-methylmercapto-4-methyl-6-oxypyrimidine (II) interacted smoothly with allylbromide forming an oxygen derivative, or the imido ester combination, *viz.*, 2-methylmercapto-4-methyl-6-alloxyprymidine corresponding to Formula III. This latter result is of especial interest and is not in accord with our previous observations. Alkylations with saturated primary halides have led to the formation of nitrogen substituted pyrimidines. The allyl group apparently has a greater affinity for the oxygen of the NH-CO grouping than for the nitrogen.

While methyl iodide interacted with the sodium salt of 2-allylmercapto-4-methyl-6-oxypyrimidine (I), giving normally a 1-methyl derivative (VIII), on the other hand, when we applied a similar reaction with allylbromide, ethylbromide and benzylchloride abnormal results were obtained. *In no case did we observe the formation of 3-substitution products.* Allylbromide interacted with the sodium salt of the pyrimidine (I) giving exclusively an oxygen derivative corresponding to Formula IX. This

¹ This question is of special biochemical interest to us because of its connection with our synthetical work, now in progress, on pyrimidine nucleosides (T. B. Johnson).

² Wheeler and Merriam, *Am. Chem. J.*, **29**, 486 (1903).

result is perfectly analogous to that obtained by the action of the unsaturated halide (allylbromide) on the sodium salt of 2-methylmercapto-4-methyl-6-oxypyrimidine (II).

Benzylchloride and ethylbromide both reacted with the sodium salt of the allylpyrimidine (I) in an analogous manner giving mixtures of their corresponding oxygen derivatives (VI) and (XI) and 1-substituted pyrimidines represented by Formulas IV and X, respectively. The structures of these various mercaptopyrimidines were established by their behavior on acid hydrolysis. A description of the properties of these various compounds and their chemical behavior is given in the experimental part of this paper. When 2-allylmercapto-4-methyl-6-oxypyrimidine (I) was allowed to interact with bromine it was converted into the saturated pyrimidine (VII). The various changes discussed above are represented by the following formulas:

Experimental.

2-Allylmercapto-4-methyl-6-oxypyrimidine (I).—This mercaptopyrimidine was prepared by digesting the sodium salt of 2-thio-4-methyluracil¹ in alcohol, with the calculated amount of allylbromide. After the reaction was complete the solution was filtered from sodium bromide

¹ List, *Ann.*, 236, 3 (1886).

and the alcohol then evaporated. The pyrimidine was obtained in a crystalline condition and was purified by recrystallization from hot water. It separated from this solvent, on cooling, in colorless needles which melted at 131° to a clear oil without decomposition. The pyrimidine is very soluble in alcohol. From 25 g. of 2-thio-4-methyl-6-oxypyrimidine we obtained 30 g. of the mercaptopyrimidine. Nitrogen determination (Kjeldahl):

Calc. for $C_8H_{10}ON_2S$: N = 15.4; found: 15.5 and 15.6.

1-Methyl-2-allylmercapto-4-methyl-6-oxypyrimidine (VIII).—One and five-tenths grams of sodium were dissolved in 75 cc. of absolute alcohol and 10 g. of the preceding 2-allylmercaptopyrimidine dissolved in the solution. An excess of methyl iodide was then added and the mixture digested until neutral to turmeric and litmus. The alcohol was then removed by heating under diminished pressure, when we obtained the methylpyrimidine mixed with sodium iodide. This residue was then triturated with water to dissolve the iodide and the pyrimidine extracted with ether. Calcium chloride formed an insoluble addition-product with this pyrimidine and consequently we were obliged to dry its ether solution over anhydrous potassium carbonate. After complete drying, the ether was then allowed to evaporate in the air, when we obtained the pyrimidine in the form of hexagonal tables melting at 43° to an oil. It is very soluble in ligroin, ethyl acetate, chloroform and benzene. Nitrogen determination (Kjeldahl):

Calc. for $C_9H_{12}ON_2S$: N = 14.3; found: N = 14.4.

Hydrolysis with Hydrochloric Acid.—Four grams of the mercaptopyrimidine were dissolved in an excess of hydrochloric acid and the solution boiled for several hours to remove the mercapto group. On evaporating to dryness we obtained 1,4-dimethyluracil¹ which melted at 256° without further purification. This pyrimidine contained a small amount of impurity which was not removed by crystallization from alcohol or water. A mixture of this substance and some 1,4-dimethyluracil (m. 258°) melted at $256-7^{\circ}$. Nitrogen determination (Kjeldahl):

Calc. for $C_6H_8O_2N_2$: N = 20.00; found: N = 20.3.

2-Allylmercapto-4-methyl-6-alloxyprymidine (IX).—This pyrimidine was formed by digesting the sodium salt of 2-allylmercapto-4-methyl-6-oxypyrimidine, in alcohol, with the calculated amount of allylbromide. After the reaction was complete the alcohol was then removed by heating under diminished pressure and the pyrimidine finally dissolved in ether and the solution dried over potassium carbonate. On evaporating the ether the pyrimidine was obtained as an oil, which showed no signs of crystallizing on long standing. No attempt was made to distil this oil but it was digested for several hours with concentrated hydrochloric acid.

¹ Behrend and Dietrich, *Ann.*, 309, 268 (1899).

Allylmercaptan was formed and after evaporation of the acid, 4-methyluracil was the only pyrimidine identified. This was purified by crystallization from hot water and did not melt below 290° . Nitrogen determination (Kjeldahl):

Calc. for $C_5H_6O_2N_2$: N = 22.22; found: N = 21.95 and 22.1.

Action of Bromine on 2-Allylmercapto-4-methyl-6-oxypyrimidine: 2-Dibromopropylmercapto-4-methyl-5-bromo-6-oxypyrimidine (VII).—This pyrimidine is formed smoothly by dissolving 2-allylmercapto-4-methyl-6-oxypyrimidine in glacial acetic acid and then adding the required amount of bromine (2 molecular proportions). The bromine was introduced by passing air through the liquid bromine and then conducting the same into the acetic acid solution. The reaction was instantaneous. After allowing to stand for 2 or 3 days the tribromopyrimidine finally deposited. The yield was about 87% of the theoretical. It was purified by crystallization from boiling 95% alcohol and separated as rosetts of needles, which melted at 160 – 165° with decomposition. Nitrogen determination (Kjeldahl):

Calc. for $C_8H_8N_2Br_3S$: N = 6.65; found: N = 6.9.

The Action of Ethylbromide on 2-Allylmercapto-4-methyl-6-oxypyrimidine.—By the action of ethylbromide on the sodium salt of this mercaptopyrimidine we obtained an inseparable mixture of 1-ethyl-2-allylmercapto-4-methyl-6-oxypyrimidine and 2-allylmercapto-4-methyl-6-ethoxypyrimidine. Two and two-tenths grams of sodium were dissolved in absolute alcohol and 15 g. of the allylmercaptopyrimidine dissolved in the solution. Ten and five-tenths grams of ethylbromide were then added and the solution warmed on the steambath until the reaction was complete. The sodium bromide was separated by filtration and the alcohol evaporated under diminished pressure, when we obtained an oil, which refused to solidify when cooled to 0° . It was dissolved in ether, dried over potassium carbonate and finally distilled under diminished pressure. We obtained 10 g. of the mixed pyrimidines boiling from 168 – 175° at 14–18 mm. This oil showed no signs of crystallizing, and a nitrogen determination (Kjeldahl) agreed with the calculated value for an ethyl derivative (13.2%). The oil was insoluble in sodium hydroxide solution. In order to determine the constitution of the ethylpyrimidines, the oil was suspended in an excess of strong hydrochloric acid, digested for 17–18 hrs. and the solution then evaporated to dryness. We obtained a mixture of 4-methyluracil and 1-ethyl-4-methyluracil. They were separated by trituration of the crude mixture with an excess of cold chloroform when the ethylpyrimidine dissolved. The insoluble material did not melt below 290° , was free from sulfur and agreed in all its properties with 4-methyluracil. The chloroform solution was evaporated to dryness and the residue of ethylmethyluracil purified by crystallization from hot water. It separated in color-

less prisms, which melted at 193–195°. ¹ The weight of purified methyluracil was 3.2 g. and of ethylmethyluracil 3.0 g. Therefore, the original oil was a mixture of approximately equal parts of 1-ethyl-2-allylmercapto-4-methyl-6-oxypyrimidine (X) and 2-allylmercapto-4-methyl-6-ethoxy-pyrimidine (XI).

The Action of Benzylchloride on 2-Allylmercapto-4-methyl-6-oxypyrimidine.—Benzylchloride reacted with the sodium salt of this mercaptopyrimidine to form two pyrimidines, *viz.*, 1-benzyl-2-allylmercapto-4-methyl-6-oxypyrimidine and 2-allylmercapto-4-methyl-6-benzoxypyrimidine. The operation was conducted as described in the preceding experiment and the following proportions were used, *viz.*, 1.5 g. of sodium, 10 g. of the allylmercapto-pyrimidine, 6 g. of benzylchloride and 75 cc. of absolute alcohol. After filtration from sodium chloride and removal of the alcohol under diminished pressure we obtained the mercaptopyrimidines in the form of a thick oil, which did not solidify on cooling. After drying in ether solution over potassium carbonate the oil was purified by distillation. It practically all boiled at 225–235° at 14–15 mm. and a nitrogen determination (Kjeldahl) agreed with the calculated value for a monobenzyl derivative.

Calc. for $C_{16}H_{16}ON_2S$: N = 10.3; found: N = 10.5.

In order to determine the composition of this mixture the oil was digested with concentrated hydrochloric acid until completely hydrolyzed and the acid solution then evaporated to dryness. A mixture of 4-methyluracil and 1-benzyl-4-methyluracil² was obtained. They were separated from each other by a fractional crystallization from water. The benzylpyrimidine was obtained in colorless prisms, which melted at 194–5°, and a mixture of this with some 1-benzyl-4-methyluracil prepared by Wheeler and McFarland³ melted at exactly the same temperature. Methyluracil was isolated in a pure condition from the aqueous filtrates and did not melt below 300°. We obtained no evidence of the presence of 3-benzyl-4-methyluracil.⁴ The weights of methyluracil and the benzylpyrimidine were about equal. Therefore, the product of the alkylation was a mixture of two pyrimidines, *viz.*, 2-allylmercapto-4-methyl-6-benzoxypyrimidine (VI) and 1-benzyl-2-allylmercapto-4-methyl-6-oxypyrimidine (IV).

Action of Allylbromide on the Sodium Salt of 2-methylmercapto-4-methyl-6-oxypyrimidine. 2-Methylmercapto-4-methyl-6-alloxy-pyrimidine (III).—The 2-methylmercapto-4-methyl-6-oxypyrimidine used in our work was prepared by alkylation of 2-thio-4-methyluracil with methyl iodide in alcoholic solution and in presence of the required amount of

¹ Hoffmann, *Ann.*, **253**, 68 (1889); Hagen, *Ibid.*, **244**, 8 (1888).

² Wheeler and McFarland, *Am. Chem. J.*, **42**, 101 (1909).

³ *Loc. cit.*

⁴ Wheeler and McFarland, *Loc. cit.*

sodium ethylate. For the alkylation, the following proportions were used, *viz.*, 15 g. of the 2-mercaptopyrimidine, 2.4 g. of sodium, 14 g. of allylbromide and 75–100 cc. of absolute alcohol. After the reaction was complete the sodium bromide was filtered off and the excess of alcohol removed in the usual manner, when we obtained the allyl derivative as a yellow oil. This was extracted with ether dried over potassium carbonate and then further purified by distillation under diminished pressure. It practically all boiled at 160–164° at 17 mm. A nitrogen determination (Kjeldahl) gave:

Calc. for $C_8H_{12}ON_2S$: N = 14.2; found: N = 14.3.

The constitution of this mercaptopyrimidine was established by its behavior on hydrolysis. It was converted smoothly into 4-methyluracil by digestion with hydrochloric acid. This was purified by crystallization from hot water and did not melt or decompose below 300°. Analysis (Kjeldahl):

Calc. for $C_5H_6O_2N_2$: N = 22.2; found: N = 22.2.

NEW HAVEN, CONN.

ON 1-PHENYL-4,5-DIHYDRO-5-OXY-3-TRIAZOLYLSULFINIC
ACID AND 1-PHENYL-4,5-DIHYDRO-5-OXY-3-
TRIAZOLYLMETHYLSULFONE.

[EIGHTEENTH¹ COMMUNICATION ON URAZOLES.]

By E. W. ESSLINGER AND S. F. ACRER.

Received November 14, 1914.

In developing the study of tautomerism as illustrated in the urazoles, it has been found² that 1-phenyl-3-thiourazole (I) apparently gives only one mono-alkyl derivative (II) when treated with an alkyl halide, diazomethane or alcoholic hydrochloric acid, or when its salts are treated with an alkyl halide or sulfate. It will be recalled that the corresponding 3-oxyurazole always yields a mixture of the 2-N-ester (V) and 3-O-ester (VI) under these conditions, the yields varying widely with the different salts and alkyl halides used. A mathematical development of our theory³ showed that the facts can be interpreted consistently on the idea that the salts of the 3,5-dioxyurazoles exist in two tautomeric⁴ forms (III) and (IV),

¹ This work was presented in June, 1912, by E. W. Esslinger as a partial fulfillment of the requirements for the degree of Master of Arts in the Johns Hopkins University. It has seemed to us wise, therefore, to submit the esters assumed to have the constitutions (II) and (XVII) to a number of reactions in order to secure more light on this important question. The first transformation carried out is the oxidation of 1-phenyl-3-thiourazole (VII), 1-phenyl-3-thiomethylurazole (XV), and 1-phenyl-3-thiomethyl-4-methylurazole (XVII). If 1-phenyl-3-thiourazole behaves normally on oxidation with potassium permanganate or hydrogen peroxide we should expect the formation first of a sulfinic acid (VIII) and then of a sulfonic derivative (IX), or even a derivative of sulfuric acid as described by Dr. H. A. Lubs in an article which will appear later. This particular reaction seems to be rather complicated, but Eßlinger has isolated a very soluble substance which seems to be a sulfinic acid, and to which we have tentatively assigned the structure (VIII). A silver salt was made which seemed to possess the corresponding formula. Furthermore, Lubs has oxidized (VII) still further and also oxidized the 1-phenyl-3-thio-4-methylurazole corresponding to (VII) and shown definitely that, *when the sulfur at -3- has no alkyl on it, the urazole can be readily oxidized to a corresponding very soluble acid*. This evidence, though preliminary, is of great importance in the following reactions:

The oxidation of (XV) and (XVII), however, is very simple, as they seem to behave like thioethers and yield sulfones. If the methyl derivative, m. p. $175-6^\circ$, obtained by the alkylation of 1-phenyl-3-thiourazole or its monobasic salt, had the sulfur free from a methyl group, as in (X), we should expect to get by the final oxidation, just as with (VII), an acid having an oxidized sulfur grouping like (VIII) or (XI). Such an acid should be *very soluble*, at least dibasic and should have at least four oxygen atoms. As a matter of fact the substance obtained is *very insoluble*, behaves like a sulfone, has only three oxygens, is a monobasic acid, forms a mono-silver salt, and behaves in every respect as if it has the structure (XVI). We must conclude, therefore, that the methyl derivative obtained by alkylating 1-phenyl-3-thiourazole, and melting at $175-6^\circ$, has the

structure (XV) and is a derivative of (I) or (VII). When the sodium salt of (XVI) is alkylated with methyl iodide a neutral substance is obtained which corresponds in all respects to (XVIII). This same substance is formed by oxidizing the dimethyl derivative (XVII) obtained by methylating 1-phenyl-3-thiourazole (VII) and having the m. p. 95–6°. That this dimethylurazole has the structure (XVII) and not (XIII) is shown by the above reasoning and the fact that one methyl is surely¹ already known to be at -4-. If the other methyl were at -2-, as in (XIII), and the sulfur were free from alkyls, oxidation should give us a *very soluble acid* like (XIV) instead of the *insoluble neutral substance* obtained (XVIII).

It must be decided at present, therefore, that 1-phenyl-3-thiourazole reacts in the enol form (VII) and yields on alkylation the mono- and dialkyl derivatives, (XV) and (XVII), having one methyl on the sulfur at (III) instead of on the nitrogen at -2-. We are planning further experiments to remove the -SCH₃ and -SO₂CH₃ groups from these urazoles, in order to obtain the corresponding oxyurazoles which have been synthesized by other methods, leaving no doubt as to their constitution.

Experimental.

1-Phenyl-5-oxy-4,5-dihydro-3-triazolylsulfonic Acid (VIII).—This compound was made by oxidizing the sodium salt of 1-phenyl-3-thiourazole, either by means of an alkaline solution of potassium permanganate or with a 30% solution of hydrogen peroxide. Both methods gave the same substance which melted at 174–178°.

I. The sodium salt of 1-phenyl-3-thiourazole in a slightly alkaline solution was treated with sufficient potassium permanganate to furnish two oxygen atoms. After all the potassium permanganate had been added, the solution was boiled, then filtered to remove the manganese hydroxide, after which it was evaporated to a small volume and acidified. On cooling 1-phenyl-5-oxy-4,5-dihydro-3-triazolylsulfonic acid crystallized out.

II. A slightly alkaline solution of the sodium salt of 1-phenyl-3-thiourazole was placed with a smaller sealed tube of 30% hydrogen peroxide in a thick walled glass tube, which was then sealed. By violent shaking the thin walled tube containing the hydrogen peroxide was broken and the two solutions were thoroughly mixed. Hydrogen peroxide in an alkaline solution decomposes rapidly, liberating a large quantity of oxygen which in this case is the active agent. After standing two days the tube was opened and no unchanged 1-phenyl-3-thiourazole was found on the addition of a slight excess of sulfuric acid. The solution was evaporated to a small volume and the same 1-phenyl-5-oxy-4,5-dihydro-3-triazolylsulfonic acid was obtained as above.

¹ Ber., 36, 3154 (1903).

Di-silver Salt of 1-Phenyl-5-oxy-4,5-dihydro-3-triazolylsulfonic Acid,

This compound was made by adding silver nitrate to an aqueous solution of 1-phenyl-5-oxy-4,5-dihydro-3-triazolylsulfonic acid. The silver salt precipitated out as a white powder that soon turned gray and when dry was dark brown.

0.3221 g. substance lost 0.0120 g. H_2O at 110° ; 0.5159 g. substance gave 0.2419 g. Ag. Calc. for $\text{C}_8\text{H}_8\text{N}_3\text{SO}_3\text{Ag}_2 \cdot \text{H}_2\text{O}$ (1 mol), 3.94; Ag_2 , 47.17; found: 3.72 and 46.88.

It is not intended by the use of the above formulas to indicate whether the water lost on heating the substance is water of crystallization or of constitution.

1-Phenyl-5-oxy-4,5-dihydro-3-triazolylmethylsulfone (XVI).—This compound was made by oxidizing 1-phenyl-3-thiomethylurazole by means of potassium permanganate as described under the preparation of 1-phenyl-5-oxy-4,5-dihydro-3-triazolylsulfonic acid. This substance differs from 1-phenyl-5-oxy-4,5-dihydro-3-triazolylsulfonic acid in that it separates from the oxidizing mixture on the addition of sulfuric acid. It was easily purified by dissolving it in dilute alkali and precipitating it with sulfuric acid. When pure it melts at $206\text{--}207^\circ$.

1.100 g. substance required 23.1 cc. $N/5$ NaOH; calc., 22.9 cc.

Silver Salt of 1-Phenyl-5-oxy-4,5-dihydro-3-triazolylmethylsulfone,

This silver salt was made by adding silver nitrate to the neutral sodium salt of 1-phenyl-5-oxy-4,5-dihydro-3-triazolylmethylsulfone. The silver salt precipitated out as a white powder, which remained unchanged when dry.

0.2317 and 0.2351 g. substance gave 0.0732 and 0.0732 g. Ag; calc. for $\text{C}_9\text{H}_8\text{N}_3\text{O}_3\text{SAg}$: Ag = 31.18; found: 31.16 and 31.13.

1-Phenyl-5-oxy-4-methyl-4,5-dihydro-3-triazolylmethylsulfone (XVIII).—This compound was made by treating the neutral sodium salt of 1-phenyl-5-oxy-4,5-dihydro-3-triazolylmethylsulfone with methyl iodide (CH_3I) in boiling alcoholic solution. After heating it for 2 hrs. the reaction mixture was evaporated to a small volume, made alkaline with sodium hydroxide and extracted with chloroform. The chloroform was carefully evaporated, the residue hydrolyzed with hydrochloric acid,

to remove any 1-phenyl-4,5-dihydro-5-methoxy-3-triazolylmethylsulfone that was formed, then made alkaline and extracted with chloroform. The residue obtained after the evaporation of the chloroform was dissolved in a small amount of alcohol, filtered, and slowly poured into water, when the 1-phenyl-5-oxy-4-methyl-4,5-dihydro-3-triazolylmethylsulfone precipitated as a white powder. When pure, this compound melted at 94-95°.

An experiment to determine the ratio of the enol to the keto dimethyl esters gave the following results:¹

Enol (about) 60%

Keto (about) 40%

I-Phenyl-5-oxy-4,5-dihydro-3-triazolylethylsulfone,

This compound was made by the same method used in the preparation of 1-phenyl-4-oxy-4,5-dihydro-3-triazolylmethylsulfone. When pure, this compound is white and melts at 199.5-200°.

Silver Salt of 1-Phenyl-5-oxy-4,5-dihydro-3-triazolylethylsulfone,

This salt was made by treating a neutral sodium salt of 1-phenyl-5-oxy-4,5-dihydro-3-triazolylethylsulfone with silver nitrate. This salt, when dry, was stable.

0.2526 and 0.4292 g. substance gave 0.0758 and 0.1289 g. Ag; Calc. for $C_{10}H_{10}N_3SO_3Ag$: Ag, 29.96; found: 30.00 and 30.03.

1-Phenyl-5-oxy-4-ethyl-4,5-dihydro-3-triazolylethylsulfone,

This compound was made in the same manner as was used in making 1-phenyl-5-oxy-4-methyl-4,5-dihydro-3-triazolylmethylsulfone. The compound was white and melted at 74 to 75°.

The experiment made to determine the ratio of the keto to the enol di-ethyl esters gave the following results:

Enol ester (about) 60%

Keto ester (about) 40%

¹ Method described in Marshall's Dissertation J. H. U., 1911.

Conclusions.

From the chemical and conductivity data we can conclude that 1-phenyl-3-thiourazole exists in solution chiefly as an equilibrium mixture represented below:

By means of acids at 125° , under pressure, an alkyl mercaptan can be split off from the products obtained by methylating or ethylating 1-phenyl-3-thiourazole. Hence the assumption that the alkyl group is attached to the sulfur at position 3 seems substantiated further.

Since we obtain *very soluble* acids, apparently sulfinic and sulfonic acids on oxidizing 1-phenyl-3-thiourazole, but obtain *insoluble* sulfone-like substances having two additional oxygen atoms on the oxidation of the alkylation products assumed to be 1-phenyl-3-thioalkylurazoles and 1-phenyl-3-thioalkyl-4-alkylurazoles, we may conclude that these alkyl derivatives have an alkyl on the sulfur at 3, and not on the nitrogen at 2, and that 1-phenyl-3-thiourazole is alkylated in the tautomeric thioenol forms given above.

THE VALENCE OF NITROGEN IN AMMONIUM SALTS.

BY WILLIAM A. NOYES AND RALPH S. POTTER.¹

Received November 18, 1914.

During the early years of the development of the theory of valence, many chemists held the view that each element has an unvarying valence. The apparent change of valence in nitrogen from ammonia to ammonium salts, and in phosphorus from phosphorus trichloride to phosphorus pentachloride was explained by calling the ammonium salts and the pentachloride molecular compounds, as distinguished from ammonia and the trichloride, in which the true valence of the elements was supposed to be shown. This view received support from the dissociation of ammonium salts and of phosphorus pentachloride in the gaseous state. Gradually, with the demonstration that phosphorus pentachloride volatilizes in part unchanged, that phosphorus pentafluoride, PF_5 , has a vapor density corresponding to its formula and, in general, that dissociation in the gaseous

¹ Presented in abstract before the American Philosophical Society, April 24, 1914. This paper is also an abstract of a thesis presented to the Graduate Faculty of the University of Illinois in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

state does not correspond to any rational distinction between unitary and molecular compounds, the view that elements may show a varying valence in their compounds and that nitrogen and phosphorus are sometimes trivalent and sometimes quinquivalent, come to be generally accepted.

More recently, Werner¹ has proposed a modified molecular formula for ammonium chloride, $H_3N \cdots HCl$. By this formula he intends to indicate that in the ammonium salts the nitrogen atom retains a normal valence of three, but that the nitrogen atom of the ammonia and the hydrogen atom of the hydrochloric acid are held together by secondary ("Neben") valences, the hydrogen and chlorine of the acid retaining essentially the same relation to each other as in the free acid.

An amino acid may, theoretically, assume in the aqueous solution the following forms: *a*, the free acid, $R \begin{matrix} \diagup CO_2H \\ \diagdown NH_2 \end{matrix}$; *b*, a cyclic salt, $R \begin{matrix} \diagup CO \\ \diagdown NH_3 \end{matrix} O$,

or according to Werner, $R \begin{matrix} \diagup CO \cdots O \\ \diagdown NH_2 \cdots H \end{matrix}$; *c*, a bimolecular or polymolecular

salt formed by the union of two or more molecules, $R \begin{matrix} \diagup CO_2-H_3N \\ \diagdown NH_3-O_2C \end{matrix} R$;

d, the ions of the acid group $R \begin{matrix} \diagup CO_2^- \\ \diagdown NH_2 \end{matrix}$ and H^+ ; *e*, the ions of the base,

$R \begin{matrix} \diagup CO_2H \\ \diagdown NH_3^+ \end{matrix}$ and OH^- ; *f*, the double, amphoteric ion, $R \begin{matrix} \diagup CO_2^- \\ \diagdown NH_3^+ \end{matrix}$.²

The "inner salt" structure was first proposed by Erlenmeyer and Siegel³ in 1875. Ten years later Ostwald⁴ noticed that solutions of glycocoll, $CH_2NH_2CO_2H$, have a very low molecular conductivity and that this is only slightly increased by dilution. He states that in its behavior it is more like a neutral salt than an acid. In 1891 Marckwald⁵ called attention to the fact that amino acids of the aliphatic series react only slowly with the mustard oils, while other primary amines react quite readily. Since the amino acids react easily in alkaline solutions, he held that the acids are, in reality, inner salts. Sakurai⁶ attempted to substantiate the "inner salt" structure on their preparation from halogen derivatives of the acids and on the resistance which amino acids offer to the formation of acid chlorides. Walker⁷ points out that conductivity determinations

⁷ *Ibid.*, 10, No. 139 (1895).

tell us very little about the structure of glycocoll, but that, since the conductivity of phenylglycocoll, $C_6H_5NHCH_2CO_2H$, is greater than that of acetic acid, it must contain a carboxyl group which ionizes. Tilden and Forster¹ showed that the amino group of amino acids may be replaced by chlorine by the action of nitrosyl chloride, and considered this an argument against the inner salt formation. Somewhat later Carrara and Rossi² based an argument for the inner salt structure on the conductivity of betaine hydrochloride, $(CH_3)_3NClCH_2CO_2H$. From the values found they considered that the salt was almost completely hydrolyzed to hydrochloric acid and betaine, $(CH_3)_3NCH_2CO$.

however, that if betaine hydrochloride is in reality hydrolyzed the conductivity of the solution should be the same as that of the equivalent amount of hydrochloric acid, while both Bredt's measurements and those of Carrara and Rossi gave a conductivity scarcely more than one-half as great. There can be no doubt, of course, that the anhydride of betaine, $(CH_3)_3NCH_2CO_2$, has the structure of a salt, but no one seems to have determined whether this is monomolecular or dimolecular. Walker⁴

has shown, however, that aminoacetic acid, $CH_2 \begin{array}{l} \diagup CO_2H \\ \diagdown NH_2 \end{array}$, is monomolecular

in aqueous solutions. Our results, given below, indicate that a solution of an amino acid which gives no inner salt may still contain the acid mostly in the monomolecular form.

Winkelblech⁵ discusses the hydrolysis of an amino acid on the basis of conductivity data for weak acids, weak bases and water. It does not seem possible from conductivity data, however, to determine whether the

acid is in the form of an inner salt, $R \begin{array}{l} \diagup CO_2 \\ \diagdown NH_3 \end{array}$, in the unionized state,

$R \begin{array}{l} \diagup CO_2H \\ \diagdown NH_2 \end{array}$ or $R \begin{array}{l} \diagup CO_2H \\ \diagdown NH_3OH \end{array}$, in the form of the double, amphoteric ion

$R \begin{array}{l} \diagup CO_2^- \\ \diagdown NH_3^+ \end{array}$, or in the form of a bimolecular salt, $R \begin{array}{l} \diagup CO_2-NH_3 \\ \diagdown NH_3-CO_2 \end{array} R$. The

hydrogen and hydroxyl ions of the amphoteric form would, of course, combine to form water and if the acid and basic functions were of equal "strength" the solution would react neutral. None of these forms would show any conductivity and, while the bimolecular form could be disting-

⁴ *Proc. Chem. Soc.*, 10, 94 (1894).

⁵ *Loc. cit.*

uished from the others by a determination of the molecular weight, it is not clear how any of the ordinary physical methods could be used to distinguish between the three forms, $R \begin{matrix} \diagup \text{CO}_2\text{H} \\ \diagdown \text{NH}_2 \end{matrix}$, $R \begin{matrix} \diagup \text{CO}_2 \\ \diagdown \text{NH}_3 \end{matrix}$, and $R \begin{matrix} \diagup \text{CO}_2^- \\ \diagdown \text{NH}_3^+ \end{matrix}$.

The form $R \begin{matrix} \diagup \text{CO}_2\text{H} \\ \diagdown \text{NH}_3\text{OH} \end{matrix}$ would have a higher molecular weight and might,

possibly, be distinguished from the other three by that means, but it could not be distinguished by conductivity measurements. It does not seem to us that the ordinary equations for hydrolysis, which Winkelblech attempts to apply, could be used in a complex case of this sort.

From the above summary it would seem that the evidence with regard to inner salt formation is not altogether satisfactory and light upon the question from an entirely different point of view is welcome. We think that we have secured this from a study of the specific rotations of a series of amino acids from camphor. The formulas and names of the compounds are given below. To bring out the relationships more clearly the specific rotations given for the salt are calculated to the basis of one gram of the free acid in 1 cc. of the solution instead of for one gram of the salt.

It will be noticed that the aminocamphonanamic acid and aminodihydrocampholytic acid are represented as having a cyclic or inner salt structure, while the aminocampholic acids are both represented as having an open structure. The evidence for these structures is based on the specific rotation of the compounds. The rotation of the sodium salt and hydrochloride of aminocamphonanamic acid are to the right while that of the anhydride, which is undoubtedly cyclic in structure, is to the left. The ammonium salt is also left handed, indicating a cyclic structure similar to that of the anhydride. The sodium salt and hydrochloride of aminodihydrocampholytic acid are right handed. The free acid and anhydride are also right handed, but with a considerably increased rotation. The sodium salt and free α -aminocampholic acid are both right handed with rotations closely alike, indicating that each has an open structure, but the anhydride, which certainly has a cyclic structure, is left handed and has a rotation very closely like that of the aminocamphonanamic acid, indicating again very clearly that the latter has a cyclic structure and that each compound contains a cycle of six atoms. The sodium salt of β -aminocampholic acid and the free acid also correspond closely in rotation, indicating

an open structure for both, while the hydrochloride and anhydride have a considerably greater rotation, as is the case with both the free aminodihydrocampholytic acid and its anhydride.

All of these observations are consistent with the hypothesis that aminodihydrocampholytic and aminocamphonan acid form cyclic salts containing cycles of six atoms, while the aminocampholic acids do not form such salts, because, if formed, they would contain cycles of seven atoms. It seems difficult to find any other simple explanation for the observations.

The results also point very strongly to the formula for ammonium salts which represents them as containing quinquivalent nitrogen and against Werner's formula. According to Werner's formula the free aminocamphonan and aminodihydrocampholytic acids would contain cycles of seven atoms,

Such a formula is quite inconsistent with all that we know about the ease with which rings of five and six atoms are formed and the comparative rarity of seven-atom rings. It is also inconsistent with the close agreement between the rotation of the aminocamphonan acid and that of the anhydride of α -aminocampholic acid. We know that the latter compound contains a six-atom ring.

Determinations of the molecular weights in aqueous solutions by the freezing point method have shown that all four of the amino acids are monomolecular in such solutions.

The following table brings out in a striking way the relations which have been found. The rotations are calculated from results obtained with solutions containing from 2.5 to 10% of the substances examined and are given on the basis of the amount of free amino acid corresponding to the compound which was present. Thus $[\alpha]_D$ for the hydrochloride of aminocamphonan acid (*i. e.*, the rotation in a 10 cm. tube of 1 g. in 1 cc.) is 25.0° but the rotation in the table is given as 30.3°, which is the calculated rotation for 1 g. of the free acid in 1 cc., after conversion into the hydrochloride.

	HCl salt.	Free acid.	HCl salt + 1 mol NaOH.	HCl salt + 2 mols NaOH.	Anhy- dride.
Aminocamphonan acid.....	30.3°	-29.2°	-28.8°	55.4°	-60.5°
Aminodihydrocampholytic acid.....	50.1°	54.7°	54.0°	20.5°	72.8°
α -Aminocampholic acid.....	53.3°	67.0°	62.4°	65.6°	-33.9°
β -Aminocampholic acid.....	49.5°	16.4°	16.7°	15.2°	66.5°

The free acids have, in each case, nearly the same rotation when prepared by the addition of one mol of sodium hydroxide to one mol of the hydro-

chloride, as when the pure acid is dissolved directly in water. The addition of a second mol of sodium hydroxide causes a large change in the rotations of aminocamphonanamic and aminodihydrocampholytic acids, evidently because the cyclic structure of the inner salt is broken down by the formation of the sodium salt, but no such change is observed with the campholic acids.

Experimental.

Aminocamphonanamic Acid, C_8H_{14} $\begin{matrix} \nearrow CO_2H \\ \searrow NH_2 \end{matrix}$. —The hydrochloride of amino-

camphonanamic acid was prepared as previously described.¹ One hundred grams of the hydrochloride were dissolved in water and a solution of sodium hydroxide added till the reaction was faintly alkaline to phenolphthalein after boiling a small portion in a test tube. The solution was then evaporated to about 100 cc. and the free amino acid obtained was filtered off and was recrystallized by dissolving in water and evaporating the solution. The yield of the crude acid was 72 g., about 82% of the theory. It is possible to recover the remainder of the acid as hydrochloride from the mother liquors. The free acid is about equally soluble in hot and cold water. Hoogewerf and Van Dorp² report a melting point of 260°. If heated rather rapidly we find that it sublimes without melting at a temperature above 300°. It is probable that the melting point reported by Hoogewerf and Van Dorp was found by heating slowly, which causes a partial conversion into the anhydride. The latter melts at 203°. Because of the melting point reported by the authors mentioned, and because of the left-handed rotation, which seemed to us, at first, anomalous for a derivative of dextracamphoric acid, the mother liquors from the preparation of the aminocamphonanamic acid were very carefully examined for a possible isomer, but none was found.

The aqueous solution of aminocamphonanamic acid, 10 g. in 100 cc. of the solution, gave a specific rotation $[\alpha]_D^{25} = -29.2^\circ$.

The molecular weight was determined with a sample which had been recrystallized six times from water, twice more than was necessary to remove all of the chlorine. A solution of the acid was mixed with ice, from distilled water, which had been broken to pieces the size of a pea and the mixture was placed in a Dewar bulb. After equilibrium was reached and the temperature had been taken, 20 cc. of the clear solution were drawn off and evaporated and the residue dried to constant weight on the water bath. The results were:

Subst., 0.304; H_2O , 16.6; depression, 0.194; mol. wt. found, 173. Calc. for $C_8H_{14}CO_2NH_2$, 171.

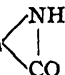

¹ *Am. Chem. J.*, **16**, 507 (1894). Formerly called aminolauronic acid. See *THIS JOURNAL*, **34**, 1067 (1912).

² *Ibid.*, **16**, 506 (1874), footnote.

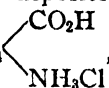

The Anhydride of Aminocamphonic Acid, C_8H_{14} , has been

prepared¹ by distilling a mixture of the hydrochloride and lime. The following method gives a nearly quantitative yield and avoids the use of a high temperature: Ten grams of the hydrochloride, 6 g. (1.5 mol) of fused sodium acetate, and 20 cc. of acetic anhydride were boiled gently in a long necked flask for about 10 min. After cooling, 10% excess of a strong solution of sodium hydroxide was added and the mixture heated on the water-bath till the liquid layer which formed at first on top was changed to a solid. The liquid layer probably consisted in part of the acetyl derivative of the anhydride, but this was not examined further. After cooling, the anhydride was separated by two extractions with ether. After two crystallizations from petroleum ether it melted quite sharply at 203°.²

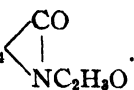

$[\alpha]_D^{29} = -60.5$, 1 g. in 10 cc. of absolute alcohol and $[\alpha]_D^{26} = -60.6$, 0.05 g. in 10 cc. of water. Noyes and Taveau³ found $[\alpha]_D^{26} = -60.1$ for a 10% alcohol solution.

Subst., 0.373, 0.750; H_2O , 20.9, 20.1; depression, 0.208°, 0.432°; mol. wt. found, 157, 159. Calc. for C_8H_{14}  : 153.

Hydrolysis of Aminocamphonic Acid Anhydride.—The anhydride was not hydrolyzed by heating with water for three days in a water-bath. Heating for three days in the water-bath with an excess of sodium hydroxide was also without effect, but when 3 g. of the anhydride were heated for 10 hrs. with 20% hydrochloric acid the solution deposited crystals of

the hydrochloride of aminocamphonic acid, C_8H_{14} , on cooling.

This gave $[\alpha]_D^{24} = 24.9$ °, proving that there is no inversion of the acid either in the formation of the anhydride or in its hydrolysis.

Acetyl Derivative of Aminocamphonic Anhydride, C_8H_{14} .

—This was prepared by boiling a mixture of 6 g. of aminocamphonic acid hydrochloride, 3.5 g. of sodium acetate and 12 cc. of acetic anhydride for 10 min. After cooling and adding enough sodium hydroxide to nearly neutralize the acetic acid and excess of acetic anhydride, the mixture was extracted with petroleum ether and the extract washed with water to remove free acid. After drying with sodium sulfate and distilling away the

² *Am. Chem. J.*, 16, 507 (1894).

³ *Ibid.*, 32, 288 (1904).

petroleum ether, a slightly yellow oil was obtained. This was distilled and the portion boiling at 260–262° was analyzed:

Calc. for $C_8H_{14}CONC_2H_3O$: N = 7.16; found: 7.05; $[\alpha]_D = +72.7^\circ$, 0.544 g. in 5 cc. of alcohol.

The substance gave aminocamphonanic anhydride melting at 201–203° by hydrolysis with sodium hydroxides.

Nitroso Derivative of Aminocamphonanic Anhydride, $C_8H_{14} \begin{array}{l} \diagup CO \\ \diagdown NNO \end{array}$.

—This was prepared by Brecht,¹ but he did not determine the specific rotation.

We found $[\alpha]_D^{24} = 153^\circ$; 0.25 g. in 10 cc. of alcohol.

It is interesting to notice that both the acetyl and the nitroso group change the negative rotation of the anhydride to a positive, the nitroso group producing a much larger effect than the acetyl group.

Cyanocamphonanic Acid, $C_8H_{14} \begin{array}{l} \diagup CO_2H \\ \diagdown CN \end{array}$, was prepared by treating

α -camphoramidic acid, $C_8H_{14} \begin{array}{l} \diagup CO_2H \\ \diagdown CONH_2 \end{array}$, with acetyl chloride, according

to the method of Hoogewerf and Van Dorp.² This gave about the same yield of crude acid which they obtained, namely, about 50%. It was thought, since the hydrochloride of the α -isoimide obtained by treating the α -camphoramidic acid with acetyl chloride is very easily hydrolyzed by water to the α -camphoramidic acid, that perhaps by suspending the isoimide hydrochloride in petroleum ether and passing in dry ammonia gas, the yield could be increased. The following procedure was used: 12.5 g. of α -camphoramidic acid and 50 g. of acetyl chloride were placed in a flask which was attached to a reflux condenser. The flask was heated on the water bath. A solution is first formed and in about two minutes the contents of flask apparently become solid. The flask and material were then cooled, the material filtered and the solid washed with carbon disulfide. Up to this point the method of procedure was just the same as given by the above mentioned investigators. Instead of adding the isoimide hydrochloride to 20% ammonia, as they did, it was shaken with petroleum ether and a slow stream of dry ammonia gas was passed through the mixture until saturation was reached. A dilute solution of ammonia was added to dissolve the ammonium salts, and from the aqueous solution the cyanoacid was precipitated with dilute hydrochloric acid. The hydrochloric acid solution must be added drop by drop or the cyanoacid will be precipitated as a gummy mass. The crystalline acid was filtered

¹ *Ber.*, 35, 1291 (1902).

² *Rec. trav. chim.*, 14, 261 (1895).

and, after drying, was weighed. 10 g., or 84%, of the theory was obtained. For purification two methods were used, one by recrystallization from hot water, which was the method used by Hoogewerf and Van Dorp, the other, by dissolving the acid in dilute ammonium hydroxide and precipitating it with dilute hydrochloric acid. By the first method from 5 g. of the crude acid 2.4 g. of acid, melting sharply at 121° , were obtained. This is the melting point found by the above mentioned investigators. By the second method, 3.1 g. of the pure product were obtained from 5 g. of the crude acid. This method is also to be preferred on account of its greater ease of manipulation.

$[\alpha]_D^{26} = 67.3^{\circ}$, 1 g. in 10 cc. of alcohol. Hoogewerf and Van Dorp¹ found exactly the same for a 6% alcoholic solution.

α -Aminocampholic Acid Hydrochloride, C_8H_{14} $\begin{cases} CO_2H \\ CH_2NH_2Cl \end{cases}$.—The only

variation from the method of preparation of Hoogewerf and Van Dorp² or Rupe and Splittgerber³ was that a somewhat larger portion of sodium was used in the reduction. 5 g. of cyanocamphonic acid were dissolved in 50 cc. of absolute alcohol and 15 g. of sodium were added in small portions, the flask being connected to a reflux condenser. During the addition of the sodium about 20 cc. more of alcohol were added. After all the sodium had dissolved water was added and the solution was evaporated until the odor of alcohol was no longer given. From this point on a method of separation and purification of the hydrochloride entirely different from that of Rupe and Splittgerber³ was used. Hydrochloric acid in slight excess was added to the cold solution and it was then extracted with ether in order to remove any unchanged cyanoacid. Upon evaporation of the ether solution it was found that about 1 g. of cyanoacid was obtained. This was used in subsequent reductions. The hydrochloric acid solution was evaporated to dryness and the residue ground up in a mortar with alcohol. The alcohol was filtered, diluted, with water and the alcohol was evaporated. The brown turbidity of the solution was then removed by filtering twice through powdered animal charcoal. The clear solution was then evaporated on the water bath until crystals started to form, when it was removed and allowed to cool and filtered. The very slightly brown crystals were dissolved in the minimum amount of hot water, filtered again through animal charcoal and after cooling, the pure white, needle-like crystals were filtered off, dried, and a melting point taken. It was found to be $248-250^{\circ}$. A portion was again recrystallized and the same melting point was given.

¹ *Rec. trav. chim.*, **14**, 26 (1895).

² *Ibid.*, **14**, 261 (1895).

³ *Ber.*, **40**, 4313 (1907).

Rupe and Splittgerber¹ give the melting point as 247–248°. The specific rotation, which had never been taken before, was determined.

$[\alpha]_D^{24} = 44.7^\circ$; 0.5 g. in 10 cc. of a solution in water.

Calc. for $C_8H_{14}(CO_2H)CH_2NH_2HCl$: Cl = 16.00; found: Cl, 16.17.

α -Aminocampholic Acid, C_8H_{14} $\begin{matrix} \diagup CO_2H \\ \diagdown CH_2NH_2 \end{matrix}$.—An attempt was made

to prepare the free acid from its hydrochloride in the same manner that aminocamphonic acid is prepared from its hydrochloride, but the free acid was apparently more soluble than sodium chloride and this method was abandoned. Instead, the hydrochloride was dissolved in water and sodium hydroxide added until an outside test with phenolphthalein showed a very faint alkaline reaction. The solution, after filtering, was evaporated to dryness and the residue was ground up in a mortar with alcohol, the alcohol filtered, diluted and partially evaporated. The slightly turbid solution was filtered through charcoal and then the solution was evaporated until only a few cubic centimeters of liquid were left, a large mass of crystals having separated during the evaporation. The crystals were filtered off and recrystallized by evaporation of the water solution, the acid being practically as soluble in cold as in hot water. This was repeated three times more and the acid then showed no trace of chlorine. The molecular weight was determined with this sample. Heated in a capillary tube no melting point was obtained but considerable decomposition took place between 300° and 320°, depending upon the rate of heating.

$[\alpha]_D^{26} = 67.0^\circ$; 0.207 g. in 10 cc. of solution.

Subst., 0.418, 0.585; H_2O , 15.6, 18.4; depression, 0.251°, 0.297°; mol. wt. found,

196, 197. Calc. for C_8H_{14} $\begin{matrix} \diagup CH_2-NH_2 \\ \diagdown (CO_2H) \end{matrix}$: 185.

α -Camphidone, C_8H_{14} $\begin{matrix} \diagup CO \\ \diagdown CH_2 \end{matrix} \rangle NH$.—This was prepared from the

hydrochloride of α -aminocampholic acid in precisely the same manner as the anhydride of aminocamphonic acid was prepared from the hydrochloride of aminocamphonic acid. After making the acetic anhydride solution alkaline with sodium hydroxide the same liquid layer was observed on the surface that was observed in the preparation of the above mentioned anhydride. This was very likely the acetyl derivative, but no attempt was made to isolate it. Practically a theoretical yield of the anhydride was given. It melts at 229–231°. Recrystallizing once from petroleum ether gave a pure product melting at 230–231°.

$[\alpha]_D^{26} = -33.9^\circ$; 0.5 g. in 10 cc. alcohol solution. Rupe and Splittgerber¹ give $[\alpha]_D = -37.2^\circ$ in a 10% solution in benzene.

¹ *Ber.*, 40, 4313 (1907).

Nitroso Derivative of α -Camphidone, C_8H_{14} $\begin{array}{c} \diagup CO \diagdown \\ \diagdown CH_2 \diagup \end{array}$ NNO.—The

α -camphidone was dissolved in hydrochloric acid (1 : 4) and a sodium nitrite solution slowly added. The yellow crystals formed were filtered, dried and recrystallized from hot alcohol. The lemon yellow, needle-like crystals gave a melting point of 125–126°. The product given by a second recrystallization showed the same melting point.

$$[\alpha]_D^{23} = -59.0^\circ; 0.25 \text{ g. in 10 cc. of alcohol.}$$

From analogy to the well-known nitroso derivatives of aminocamphonanilic and dihydroaminocampholytic acid anhydrides, it was not thought necessary to analyze the compound for identification.

Aminodihydrocampholytic Acid, C_8H_{14} $\begin{array}{c} \diagup NH_2 \diagdown \\ \diagdown CO_2H \diagup \end{array}$.—This acid was pre-

pared in the same manner as described by Noyes¹ except that a more elaborate method was followed in recovering the last traces of the acid. The procedure followed was identical with that for the preparation of aminocamphonanilic acid from α -camphoramidic acid, except that β -camphoramidic acid was used and, instead of adding sufficient hydrochloric acid to give the acid hydrochloride, only enough was added to give a solution exactly neutral to phenolphthalein. After this point the solution was evaporated until the sodium chloride was starting to come down. The crystals of the amino acid were then filtered off and to the filtrate an excess of hydrochloric acid was added and the whole evaporated to dryness, and the residue extracted with alcohol. Since the dihydroaminocampholytic acid is quite easily esterified, the alcoholic solution was diluted with considerable water and just enough sodium hydroxide solution added to give a solution neutral to phenolphthalein. It was then partially evaporated and the amino acid filtered off. An excess of hydrochloric acid was added to this filtrate and the same procedure followed as above. Since the acid is no more soluble in hot than in cold water and is not soluble in any other solvent it must be purified by dissolving in water and partial evaporation. For ordinary purposes one recrystallization is sufficient. For taking the molecular weight and rotations an acid was used which had been recrystallized six times, two more times than was necessary to free it from traces of chlorine.

$$[\alpha]_D^{25} = 54.7^\circ; 0.5 \text{ g. in 10 cc. of water solution. Noyes and Phillips}^2 \text{ give } [\alpha]_D =$$

¹ *Am. Chem. J.*, 16, 503 (1894).

² *Ibid.*, 24, 290 (1900).

53.7° for the saturated solution (about 7.5%). Subst., 0.415, 0.613; H₂O, 20.5, 21.2; depression, 0.199, 0.278; mol. wt. found, 187, 191; Calc. for C₈H₁₄ $\begin{matrix} \text{NH}_2 \\ | \\ \text{CO}_2\text{H} \end{matrix}$: 171.

Aminodihydrocampholytic Acid Hydrochloride, C₈H₁₄ $\begin{matrix} \text{NH}_3\text{Cl} \\ | \\ \text{CO}_2\text{H} \end{matrix}$.—A

few grams of the free acid were shaken with a few cc. of water and sufficient hydrochloric acid was added to give a green color to methyl violet paper. The solution was then partially evaporated and upon allowing to cool the hydrochloride separated. It was filtered and recrystallized from hot water. A melting point of 262–263° was found. Recrystallizing again gave a product melting at 261–262°, which is the same as that reported by Noyes.¹

$[\alpha]_D^{26} = 41.3^\circ$; 1 g. in 10 cc. of water solution.

Aminodihydrocampholytic Acid Anhydride, C₈H₁₄ $\begin{matrix} \text{NH} \\ | \\ \text{CO} \end{matrix}$.—This sub-

stance was prepared either by treating the free acid with acetic anhydride or by treating the hydrochloride of the acid with sodium acetate and acetic anhydride and subsequently heating the mixture with an excess of sodium hydroxide. In the latter method it is probable that the acetyl derivative is formed, as the similar liquid layer was always formed on addition of the excess of sodium hydroxide to the acetic anhydride solution. The latter method of preparation has the advantage of allowing quite impure hydrochloride to be used. The melting point, 188–189°, and the specific rotation, $[\alpha]_D^{30} = 72.8^\circ$, have already been published.²

Nitroso Derivative of Aminodihydrocampholic Acid Anhydride,

C₈H₁₄ $\begin{matrix} \text{N NO} \\ | \\ \text{CO} \end{matrix}$.—Since the rotation of this substance had never been

reported it was thought desirable to obtain it. It was prepared according to a method previously reported.²

$[\alpha]_D^{26} = -83.3^\circ$; 0.25 g. in 10 cc. of absolute alcohol solution.

Cyanodihydrocampholytic Acid.—Hoogewerf and Van Dorp³ prepared this acid in just the same manner that they prepared the cyanocamphonic acid. Rupe and Splittgerber⁴ proceeded in essentially the same manner. Starting with 12.5 g. of β-camphoramidic acid and proceeding in precisely the same manner as in the preparation of the cyanocamphonic acid, 9.5 g. of crude acid were obtained, which is an 80% yield. There was not nearly as much tendency to form a gummy pre-

¹ *Am. Chem. J.*, 16, 504 (1894).

² Noyes and Potter, *THIS JOURNAL*, 34, 1072 (1912).

³ *Rec. trav. chim.*, 14, 267 (1895).

⁴ *Ber.*, 40, 4313 (1900).

cipitate as was noted in the case of the cyanocamphonic acid. The crude acid was purified by dissolving in 8% ammonia and precipitating with hydrochloric acid. One such procedure sufficed to bring the melting point up to 109–110°. A portion was recrystallized again in the same manner but no change in the melting point was observed. The above is the melting point observed by Hoogewerf and Van Dorp.¹

$[\alpha]_D^{22} = 25.3^\circ$; 0.6 g. in 10 cc. of alcohol solution. Hoogewerf and Van Dorp give the specific rotation $[\alpha]_D = 18.12^\circ$ for a 6% alcohol solution.

Since they purified their acid by recrystallization from hot water, in order to clear up the remote possibility of this causing the difference in the rotation, some of the crude acid was purified by their method, but a rotation taken after the fourth recrystallization, gave a value $[\alpha]_D = 25.2^\circ$ and after the fifth recrystallization $[\alpha]_D = 25.3^\circ$, so there is little doubt but that this is the correct value.

β -Aminocampholic Acid Hydrochloride, C_8H_{14} $\begin{matrix} \swarrow NH_3Cl \\ \searrow CH_2CO_2H \end{matrix}$.—Starting

with cyanodihydrocampholytic acid the procedure for the preparation, separation, and purification of this substance was the same as the preparation of the α -aminocampholic acid hydrochloride. It was found, however, that the reduction in the case in hand was not as complete as with the cyanocamphonic acid. It was found more advisable to simply separate the unchanged cyanoacid by extraction of the acid solution with ether than to use more sodium and alcohol. The β -aminocampholic acid hydrochloride is somewhat less soluble than its isomer and hence it is more easily purified. After two recrystallizations its melting point was 218–220°.

$[\alpha]_D^{26} = 41.3^\circ$; 0.5 g. in 10 cc. of water solution.

β -Aminocampholic Acid, C_8H_{14} $\begin{matrix} \swarrow NH_2 \\ \searrow CH_2CO_2H \end{matrix}$.—About 5 g. of the pure

hydrochloride were dissolved in the minimum amount of water and sufficient strong sodium hydroxide solution (3 cc. = 1 g.) was added to give a solution neutral to phenolphthalein. The free acid, which was precipitated, was filtered, dissolved in hot water, partially evaporated and filtered. This was repeated until a substance free from chlorine was obtained, three recrystallizations in all being required.

$[\alpha]_D^{26} = 16.4^\circ$; 0.25 g. in 10 cc. of solution.

Subst., 0.318, 0.389; H_2O , 22.1, 21.8; depression, mol. wt. found, 199, 197. Calc. for

the β -aminocampholic acid hydrochloride in just the same manner as the α -camphidone was prepared from the α -aminocampholic acid. A melting point of $234-235^\circ$ was found and a specific rotation $[\alpha]_D^{24} = 63.2^\circ$; 0.25 g. in 5 cc. of alcohol solution. Rupe and Splittgerber¹ report a melting point of 225° and its specific rotation $[\alpha]_D = 66.5^\circ$ for a 10% solution in benzene. An analysis of the compound was made.

Nitroso Derivative of β -Camphidone, $C_8H_{14} \begin{array}{c} \diagup CH_2 \diagdown \\ \diagdown CO \diagup \end{array} N NO$.—The β -

camphidone was dissolved in dilute hydrochloric acid (1 : 4) and a sodium nitrite solution was added. The yellow precipitate was filtered and recrystallized from alcohol two times, when a melting point of $164-165^\circ$ is given. A portion recrystallized a third time showed the same melting point.

$[\alpha]_D^{23} = 103^\circ$; 0.25 g. in 10 cc. of solution.

Summary.

It is shown in this paper that the specific rotations of some amino derivatives of camphoric acid are consistent with the view that those amino acids which can form cyclic salts containing quinquevalent nitrogen and

a ring of six atoms form salts having the general formula $R \begin{array}{c} \diagup CO \diagdown \\ \diagdown NH_3 \diagup \end{array} O$

in aqueous solutions. Amino acids which would give a ring of seven atoms in forming a cyclic salt appear to exist in solution as compounds of the

form, $R \begin{array}{c} \diagup CO_2H \diagdown \\ \diagdown NH_2 \diagup \end{array}$. These relations furnish strong evidence that nitrogen

is in reality quinquevalent in ammonium salts and that the hydrogen of the acid combines with the nitrogen instead of remaining combined with the acid radical, as Werner has supposed.

Several new compounds have been prepared and the specific rotations of a number of known compounds have been determined.

ON THE PRESENCE OF HISTIDINE-LIKE SUBSTANCES IN THE PITUITARY GLAND (POSTERIOR LOBE).

By T. B. ALDRICH.

Received November 5, 1914.

In 1896, A. Kossel discovered among the cleavage products of sturine

¹ Ber., 40, 4313 (1907).

a line. Later this compound was found among the cleavage products of complex proteins when these were subjected to hydrolytic or tryptic digestion.³

According to Pauly,⁴ a solution of histidine made alkaline with sodium carbonate gives a very beautiful diazo reaction with diazobenzene sulfonic acid, which is deep cherry-red in dilutions of 1 : 20,000 and still markedly red in 1 : 100,000. Furthermore it is stated that, with the exception of tyrosine, no other cleavage product from protein, among a large number tested, gives such a color reaction, and that not only can histidine be detected by means of this reaction when mixed with other cleavage products, but also when in the original protein before cleavage, where it is united with other groups, providing the tyrosine is removed or changed so as not to react with this reagent.

As far as investigated by Pauly no other proteid cleavage product outside of histidine and tyrosine gives this reaction. Nearly all give a lemon yellow color in soda solution; such color being given, according to Pauly, by glycocol, alanine, leucine, valine, serine, lysine, ornithine, arginine, asparagine, glutamic acid, cystine, and hippuric acid, while with pyrrolidine carboxylic acid and tryptophane no reaction is given. Glucosamine, phenylalanine and oxypyrolidine carboxylic acid, as well as the cleavage products obtained by Skraup⁵ from caseine were not available to Pauly, but he states that it is not to be supposed that an exception would be found among these products.⁶

In the diazo-reaction we have, therefore, a positive means of determining whether protein or protein cleavage products contain histidine or tyrosine, especially as these bodies give a positive reaction where Millon's test is practically negative. The greatest importance seems, however, to lie in the fact that this reaction shows the presence of histidine and tyrosine in protein-like combination. Whenever a protein substance gives Pauly's reaction, then either tyrosine or histidine has been demonstrated among the hydrolytical cleavage products of this protein; while in other proteins where the diazo-reaction was negative these bodies were absent.

Pauly's method⁷ of preparing diazobenzene sulfonic acid (which should be prepared fresh every time) and his directions for applying the test are as follows:

¹ *Z. physiol. Chem.*, 22, 182 (1896).

² Hedin, *Ibid.*, 22, 191 (1896).

³ Kutscher, *Ibid.*, 25, 195 (1898).

⁴ *Ibid.*, 42, 513 (1904).

⁵ *Ber.*, 37, 3 (1896).

⁶ My experience with Pauly's histidine test has shown me that other bodies besides tyrosine and histidine respond to this test, giving a reddish color that might be confusing. Among the bodies tested may be mentioned *p*-oxyphenylethylamine and β -iminazolyethylamine.

⁷ Pauly, *Loc. cit.*

1. Preparation of Diazobenzenesulfonic Acid.—Two grams of finely powdered sulfanilic acid are mixed with 3 cc. of water and 2 cc. concentrated hydrochloric acid, forming a thick paste. To this is added in small portions, in less than a minute, cooling after each addition, a gram of potassium nitrite dissolved in 1–2 cc. of water. The sulfanilic acid, for the most part, passes rapidly in solution and there is formed a thick, white crystalline precipitate of diazobenzene sulfonic acid which, after a few minutes, is filtered off by suction and washed with a little cold water. Any unchanged sulfanilic acid does not influence the reaction.

2. Reaction with Histidine.—To the solution to be tested, having demonstrated the absence of tyrosine by Millon's reagent, an excess of sodium carbonate (preferred to caustic soda) is added, and then 3–5 cc. of an alkaline carbonate solution of a few centigrams of the diazobenzene sulfonic acid prepared at the time of testing. Within three minutes at the longest, usually immediately, a dark cherry-red color appears, which even by dilution with many times its volume of water, retains its red color and does not shade into yellow. By acidulating, the color passes into a pure orange color.

Quite recently, K. Inouye,¹ working in Kossel's laboratory, published a method for detecting histidine in the presence of tyrosine, employing the above reaction. According to this investigator, the reaction is also given even when histidine is in combination with the protein molecule, and were it not for the fact that tyrosine, free or attached to protein, gives a very similar red color reaction with diazobenzene sulfonic acid, it would be a comparatively simple matter to detect histidine, just as tyrosine and tryptophane are recognized by color tests.

Since tyrosine gives with diazobenzene sulfonic acid, in alkaline solution, a color reaction that can not be distinguished from that of histidine, Inouye modified the test so as to eliminate the tyrosine from the reaction. This modification was brought about by benzoylating in alkaline soda solution.

If one shakes a solution of tyrosine with a few drops of benzoylchloride until the odor of the chloride has disappeared, after making alkaline with soda solution, the addition of diazobenzene sulfonic acid to the filtrate does not produce the characteristic color. If, on the other hand, one benzoylates histidine by the same process, the color reaction persists.

It was expected, according to Inouye, that this reaction for recognizing histidine would be applicable when histidine was united with protein or other complexes; but this expectation was not realized; for, after benzoylating such bodies, the color reaction could not be obtained, and it was found necessary to hydrolyze these substances either with the help of acids or by digestion with trypsin in order to establish the presence of histidine.

¹ *Z. physiol. Chem.*, 83, 79 (1912).

Having observed several years ago that pituitary preparations, obtained from the anterior lobe, gave a marked histidine reaction, I was lead to investigate the posterior lobe, but at that time, no method was known for detecting the presence of tyrosine. On the appearance of Inouye's communication referred to above, I concluded to use his method for detecting the presence of histidine in this lobe, the results of which investigations are given below:

Experimental.

The material employed was the desiccated defatted posterior lobe of the pituitary gland (consisting for the greater part of protein) prepared in the usual way, and a purified product soluble in water. (Three tests were made in all.)

Hydrolysis by Acid.—(1) 0.5 g. of the desiccated product was boiled for 5 hrs. (employing a return condenser) with 100 cc. of water, to which was added 2.5 cc. of concentrated hydrochloric acid. It was then evaporated on the steam bath to a syrupy consistency, taken up in water, an excess of lead oxide added, and the mixture warmed on the steam bath. After cooling it was made alkaline with sodium carbonate solution, filtered, and brought up to 80 cc.

(a) 10 cc. of the above were taken (representing 63 mg. of the original powder), 0.5 cc. saturated sodium carbonate solution and then 3 drops of benzoyl chloride were added and the mixture was agitated until the odor of the chloride had disappeared. It was then filtered and Pauly's test applied as follows:

5 cc. (32 mg.) + 4 drops of sodium carbonate saturated solution + 30 mg. of diazobenzene sulfonic acid either in solid form or dissolved in water. *Color reaction very pronounced.*

(b) 10 cc. + 1½ cc. saturated sodium carbonate solution + 15 drops of benzoyl chloride, etc. *Reaction pronounced but not as strong as by (a).*

(2) 0.5 g. of the perfectly soluble product, treated as by (1). Made up to 80 cc.

(a) 10 cc. taken + 1½ cc. of saturated sodium carbonate solution + 15 drops of benzoyl chloride, etc., etc.

Pauly's reaction pronounced, but less so than the original product.

Without Hydrolysis.—(3) 0.5 g. (perfectly soluble product) dissolved in 25 cc. H₂O, 3 cc. of saturated sodium carbonate solution added then 20 drops of benzoyl chloride. The resulting solution worked up in the usual way, gave a strong Pauly's reaction.

(4) Repeated (3) *Pauly's reaction pronounced.*

Hydrolysis by Trypsin.—(1) 0.2 g. pancreatin was agitated with 40 cc. of a 0.5% sodium carbonate solution.

(a) To 20 cc. of the above was added 0.5 g. of desiccated posterior lobe powder, and a few drops of chloroform. Placed in incubator for about 2 days.

(b) The remaining 20 cc. of (5) was also placed in incubator, a little chloroform being added.

Both (a) and (b) were agitated from time to time.

At the end of 2 days both solutions were evaporated (after neutralizing with hydrochloric acid) to a small volume, made alkaline, then benzoylated and eventually filtered. Both gave pauly's reaction, but the color given by (a) was more intense.

It might be stated at this point that both powders gave Millon's test before as well as after hydrolysis; but that after benzoylating, this reaction was always negative.

In the above experiments I have purposely used a large excess of benzoyl chloride and sufficient sodium carbonate solution to maintain an alkaline reaction. Inouye states that he used only a few drops; but in every case after thorough benzoylating I found even with a large excess of benzoyl chloride that the solution gave a positive reaction. In some instances the color was not as pronounced as one would expect, but this might be accounted for by the larger amount of benzoyl chloride used, or the fact that all was not decomposed, or that the presence of benzoic acid or its salts influenced the same.

One would conclude from the above, if Inouye's observations are correct, that histidine is present in the above preparations, prepared from the pituitary gland, were it not for the fact that the solutions before or after hydrolysis or after benzoylating failed to give in my hands Weidel's reaction as modified by Fisher or Knoop's bromine reaction. Whether we are justified, however, in drawing this conclusion is questionable, for it may be assumed that other bodies are present which interfere with the reaction or that histidine is present in too small an amount.

Under hydrolysis by trypsin the presence of a small amount of histidine in the *control* is explained by its presence in the pancreatin employed.

From (3) without hydrolysis, it would seem that at least one of the histidine-like substances in the pituitary gland (posterior) is not united to protein, for after benzoylating, employing an excess of sodium carbonate, the filtrate gave a strong Pauly's reaction. It is quite probable that we have a free and possibly a combined histidine or histidine-like compound. We are also confronted by the possibility of several substance of this nature being present. This latter view having support from the work of Fühner¹ who claims to have isolated four distinct substances from the posterior lobe of the pituitary gland, all of which give Pauly's reaction.

What compound or compounds we have to deal with here is suppositional at present, although evidence seems to be accumulating that points not to histidine but to some histidine-like compounds similar to histamine.² This view is also shared by Fühner³ who says: "According to the work of others and myself I am led to conclude that histamine and the active principle of the posterior lobe of the gland are probably not identical; but pharmacologically directly related."

Conclusions.

1. It would seem that histidine (or some such compound or compounds) is contained in the desiccated posterior lobe of the pituitary gland.
2. These substances are probably in a more or less free state, or in some combination other than protein.

¹ *Deutsche Med. Wochschr.*, 39, 491 (1913).

² Histamine is the commercial name for β -Iminazolylethylamine.

³ *Münch. Med. Wochschr.*, 599, 852 (1913).

3. The compounds giving Pauly's reaction are probably not histidine, since Weidel's reaction, as modified by Fischer, or Knoop's reaction with bromine were both negative.

4. Pauly's reaction is not a specific reaction for histidine, unless other compounds such as *l*-tryptophan, *o*-oxyphenylethylamine, β -iminazolyethylamine, etc., are excluded. The reaction for a class of compounds.

TRI-AMMONIUM CITRATE.

By ROBERT A. HALL.

Received November 20, 1914.

The ammonium salts of citric acid were seemingly first investigated by Heldt¹ in 1843, although in Berzelius' *Lehrbuch der Chemie* IV the statement is made that these compounds are very difficult to prepare and that no analysis of them had been made. Heldt's method of preparation was to neutralize a solution of citric acid with ammonia and by evaporation crystallize out the salts. His efforts to obtain the monoammonium citrate were unsuccessful, as his thick syrupy liquid always gave star-shaped groups of crystals containing varying amounts of ammonia. With the diammonium citrate he was more successful, as he obtained this salt in two separate, distinct crystalline forms. From a strong, concentrated solution after standing some hours, there separated out a mass of interlaced rhomboidal prisms; but upon slow evaporation in the cold winter air, the salt separated at the bottom of the vessel as a ring of massed oblique rhomboidal prisms with rectangular sides and semi-circular back-sides. In their composition both salts were identical and afforded a very interesting example of dimorphic organic compounds. Both crystalline forms rapidly absorbed moisture from the air and were soluble in boiling alcohol from which, upon cooling, they separated as oily drops. Their taste is agreeably acid with a cooling, bitter after effect. They were dried by pressing between filter paper and an elementary analysis made of their hydrogen and carbon content; the nitrogen was determined by precipitation as platinum ammonium hydrochloride. Both crystalline forms were found to have the composition represented by the formula $(\text{NH}_4)_2\text{C}_6\text{H}_8\text{O}_7$, that is, both were the diammonium citrate. Both salts were stable on heating to 100°.

Heldt's efforts at preparing the triammonium citrate were unsuccessful. He attempted to prepare this salt by evaporating a citric acid solution saturated with ammonia, but obtained the diammonium citrate. A

¹ Heldt, *Lieb. Ann.*, 47, 167 (—).

boiling alcoholic solution of citric acid, neutralized with ammonia, became cloudy upon cooling and deposited the salt as oily drops which did not crystallize even upon long standing.

Heusser,¹ in 1853, was evidently unacquainted with Heldt's earlier work on the ammonium citrates, for he says, "Concerning these salts (Citrates of Ammonium) I find nothing in the literature other than the observation in Berzelius's *Lehrbuch der Chemie* IV that they can be prepared unmixed only with great difficulty and no analyses thereof have been made." He attempted the preparation of the ammonium citrates but, in so far as the preparation of the triammonium citrate was concerned, he was no more successful than Heldt had been. He obtained the diammonium citrate and a compound that was probably a mixture of the di- and triammonium salts. His methods were essentially the same as those of Heldt.

F. Sestini,² in 1879, prepared a *neutral ammonium citrate* in crystalline form by neutralizing a solution of citric acid with ammonia and evaporating this solution over quick-lime in an atmosphere of ammonia. The crystals thus obtained were dried between filter paper and analyzed, the ammonia content and water of crystallization only being determined. The salt had approximately the composition represented by the formula $(\text{NH}_4)_3\text{C}_6\text{H}_5\text{O}_7 + \text{H}_2\text{O}$, that is, the salt was triammonium citrate with one molecule of water of crystallization. The crystals were monoclinic and were very unstable, going over into the diammonium citrate upon being dried at $105\text{--}110^\circ$.

Van Itallie,³ in 1908, for the purpose of investigating the failure of calcium to produce a precipitate when added to an ammoniacal solution containing oxalate and citrate, repeated the preparation of triammonium citrate by Sestini's method and with the same results. He says, "The compound is not easy to purify for analysis, as is easily understood, because it is so hygroscopic and so easily dissociated." In his analysis he determined the citric acid and ammonia content of his salt, as well as the water of crystallization. He, too, obtained the triammonium citrate with one molecule of water. From the data obtained in his physical-chemical measurements, using Schreinemaker's "Reste-Methode" of plotting his curves, he demonstrated that the triammonium citrates containing one or more molecules of water must necessarily be unstable.

The writer first prepared the salt, normal triammonium citrate, in 1911, shortly after the completion of his investigations which were published in the papers, "The Physical Properties of Aqueous Solutions Containing Ammonia and Citric Acid"⁴ and the "Preparation of Neutral

Ammonium Citrate Solutions by the Conductivity Method."¹ The salt thus obtained reacted alkaline, although the analyses showed it to have the composition of normal triammonium citrate. As this was contradictory to all the literature then existing on the subject, it was deemed advisable to make further investigation. In the spring of 1912, further samples of the salt were made, analyzed, and certain physical and chemical properties were observed.² The method of preparation and general properties of the salt were reported, for record, at the meeting of the Academy of Science of St. Louis, April 21, 1913.³ An informal oral announcement of the preparation and properties of the salt was also made at the following May meeting of the St. Louis Section of the American Chemical Society. Publication was deferred, as it was desired to continue the investigation of the salt along the following lines: (1) As to its physical-chemical properties—it was deemed necessary to determine experimentally the concentration of the NH_3 and citric acid ions in both a dilute solution and in a solution of the concentration used in the fertilizer analysis; also, to ascertain by determinations of the ionization constants the proper indicator to be used in testing the neutrality of the so-called "neutral" ammonium citrate solutions. (2) The character and effect of the growth that so frequently occurs in so-called neutral solutions of ammonium citrate. (3) The pharmacological properties of the salt.

In the summer of 1913 the investigation of the physical chemical properties had scarcely been begun in the Kent Chemical Laboratory, University of Chicago, when Dr. Hildebrand's paper, "Some Applications of the Hydrogen Electrode in Analysis, Research, and Teaching"⁴ appeared. Hildebrand had anticipated a part of the investigation planned and had announced his intention of investigating and determining the proper indicator for concentrated solutions of neutral ammonium citrate, so this part of the research was abandoned. The recent appearance of his paper on "The Preparation of 'Neutral' Ammonium Citrate"⁵ enabled me to employ his results in the examination of the salt under investigation and to complete that part of it. Although the investigation of the growth formation in the solution and the pharmacological properties of the salt is still incomplete, yet the importance of the salt, to the fertilizer chemist in particular, is thought to be sufficient justification for publishing the results so far obtained.

Hantzsch,⁶ in 1902, found, in his investigations of the behavior of weak

acids and pseudo-acids towards ammonia, that, by passing perfectly dry ammonia gas into solutions of weak organic acids and pseudo-acids in perfectly anhydrous indifferent solvents as ether or benzol, the ammonium salts of these weak acids and pseudo-acids and tautomeric forms of chloroamids, nitro derivatives, etc., hitherto regarded as unstable because of the dissociating effect of water, could be prepared and obtained pure in quantity. If proper care were taken to keep every trace of water from the compound until it had been freed from the mother liquor and perfectly dried, then these bodies were unaffected by moisture and could be freely exposed to the air. This suggested to me that triammonium citrate could be prepared by passing dry ammonia gas into a solution of anhydrous citric acid in an inactive anhydrous solvent, as ether or alcohol. This could be done by dissolving the anhydrous citric acid (made anhydrous by carefully heating the acid, *in vacuo*, to its melting temperature and carefully maintaining this temperature until the water of crystallization was completely removed) in an anhydrous indifferent solvent and then passing through the solution in excess a stream of perfectly dry ammonia gas. Since the diammonium citrate is soluble in boiling alcohol,¹ absolute alcohol probably could preferably be used as the solvent and precipitation would not occur until the formation of the triammonium citrate began. Moreover, only the pure triammonium salt would be obtained if the solution were kept at the boiling point until the acid had been completely converted into the normal salt. The yield would be quantitative. The normal salt could be freed from its mother liquor by decantation and by repeated washings with the anhydrous solvent finally removing the last trace of the solvent by suction on the filter pump. The salt, being thus perfectly dried, should be stable; it could then be exposed to the moisture of the air without undergoing decomposition, etc. The solvent and washings could be freed from ammonia and recovered in the usual way, thus reducing the loss incurred in the preparation to that of the excess of ammonia gas used (and even this loss could be prevented, if desired, by recovery of the ammonia). Results obtained fully justified these conclusions.

Experimental.

Preparation of the Normal Triammonium Citrate Salt.—1. Citric acid was freed from its water of crystallization by heating it to 150°, the melting point of the acid. The temperature was not allowed to go much above this point as the acid is decomposed by a higher heat. The removal of the water of crystallization was facilitated by the use of the vacuum pump. A weighed amount of this water-free acid was placed in a round bottom flask whose mouth was sufficiently large to permit the use of a rubber stopper through which three tubes passed. One tube was

¹ Heldt, *Loc. cit.*

for the admission of the ammonia gas; this tube extended nearly to the bottom of the flask and was slightly bent outward to avoid coming in contact with the extended flanges of the stirrer when in motion. Through the center of the stopper passed the stirrer which was propelled by a motor of a size sufficient to preclude the probability of the stirrer stopping during the experiment. The third opening was for the entrance of the lower end of the reflux condenser tube, which served the double purpose of an exit tube for the excess of ammonia gas and also for the condensation and return into the flask of the alcohol used as solvent, thus preventing the loss of alcohol. The upper end of the condenser was connected with a tightly fitting tube which conducted the excess ammonia out of doors. The ammonia gas was obtained from a tank of liquid ammonia, or was prepared by allowing strong ammonia water to drop into a flask containing solid sodium hydroxide and ammonium chloride. In either case, for the purpose of completely drying the ammonia, the gas was first passed through a reflux condenser and then through several upright towers filled with sodium hydroxide sticks. Absolute alcohol, distilled over sodium, sufficient to dissolve completely the citric acid and also to cover completely the stirrer when in motion, was added and brought to the boiling temperature by heating on an electric bath. Ammonia gas was then slowly bubbled into the boiling solution which, throughout the course of the experiment, was vigorously stirred by the electrically propelled stirrer. For some few minutes, dependent upon the concentration of the acid solution and upon the rate of admission of the gas, no precipitation occurred. This was as expected and was probably due to the formation of the mono and diammonium citrates which are soluble in boiling alcohol.¹ As soon as the formation of the triammonium citrate began, precipitation occurred and continued until all the acid had been converted into triammonium citrate. When the precipitation was completed the heat was discontinued, but the ammonia gas was allowed to pass through the solution until the flask had become entirely cool. This served to prevent air bearing water vapor from entering the flask as the flask cooled. The supernatant liquid was decanted from the salt which was washed several times by decantation with absolute alcohol, until the washings were free from ammonia, the salt then being pressed dry on the Büchner funnel, using the thin rubber sheet cover with the suction pump as suggested by Cortner.² The salt was further pressed out on a clay plate, dried for an hour on a *dry* steam bath, and then placed in a desiccator over sulfuric acid for 24 hrs. The yield of triammonium citrate was quantitative. The alcohol used as solvent and washings was freed from ammonia and recovered in the usual

¹ Heldt, *Loc. cit.*

² THIS JOURNAL, 36, 1967 (1914).

way, thus making the only loss in the preparation that of the excess of ammonia used.

2. The method of preparation was varied by substituting for anhydrous citric acid purest citric acid, containing one molecule of water of crystallization. Otherwise the preparation was carried out as given above. A salt as pure and as stable as that obtained from the anhydrous acid was obtained. The yield, however, was only 85%, as much of the salt adhered to the sides of the flask.

3. Again the method of preparation was varied by omission of the use of the (electrically propelled) stirrer. The flask was shaken by hand from time to time. There was observed a tendency of the precipitate to clog and stick to the walls of the flask. The flask was tightly corked up and allowed to stand for a week. It was found that the salt obtained was the normal triammonium citrate. The yield was not over 75%.

4. Another variation in the method of preparation was introduced, the substitution of ordinary 95% alcohol for the absolute alcohol used above, the other conditions remaining as given in the first method of preparation. From 60 g. of anhydrous citric acid about 30 g. of the normal salt was obtained. As the mixture of the di- and triammonium citrates adhered closely to the walls of the flask, it was easy to separate the pure salt.¹

5. Dry ammonia gas was passed into a cold anhydrous alcoholic solution of citric acid; precipitation occurred at once. The precipitate was very viscid and adhered to the walls of the flask and to the tube admitting the ammonia when the flask was shaken. A small amount of the precipitate was removed and, after being freed from the mother liquor, was found to be acid to litmus. The salt thus separated out was either the mono- or diammonium citrate—probably a mixture of the two. It was very deliquescent and unstable.² The passage of the ammonia was continued for several hours. The contents of the flask became warm from the heat of the reaction. A small sample was then removed from the flask and found to react acid. The flask was tightly corked and set aside for a week. It was then found that the salt had an alkaline reaction to rosolic acid. The salt was washed and dried as given above and was found to be triammonium citrate. The yield was not good.

Other solvents of citric acid, as ether, acetone, etc., were substituted for alcohol but were found to be unsatisfactory in that the insolubility of the mono- and diammonium citrates in these solvents led to their pre-

¹ While it has not been put to the experimental test yet, it is very likely that the citric acid with its water of crystallization can be used in this method also.

² Investigation of the mono- and diammonium citrates is being continued in this laboratory.

precipitation along with the normal salt and thus gave mixtures instead of the pure salt.

Properties of Triammonium Citrate.—Triammonium citrate, prepared from a solution of the anhydrous citric acid in absolute alcohol or from a solution of the pure citric acid containing water of crystallization, is a beautiful white, crystalline salt. It is stable in so far that it can be exposed to the air for more than 24 hrs. without appreciable change, can be heated for an hour or more on a dry steam bath, or kept indefinitely in a desiccator over sulfuric acid. Upon prolonged heating on the steam bath or prolonged exposure to the air the salt loses ammonia and doubtless passes over into the diammonium citrate.¹ It is exceedingly soluble in water and can not be recrystallized from its water solution by evaporation. When a saturated water solution, cooled in a freezing mixture of ice and salt, is poured into absolute alcohol similarly cooled, a mass of long, fine crystals is obtained. The crystals were unstable and were not analyzed.¹ They are probably the triammonium citrate with one or more molecules of water of crystallization.² (It is hoped to take advantage of the winter cold of Minnesota to prepare and to isolate this salt in a pure form by carrying out the preparation altogether in the out door cold.) If a saturated water solution of triammonium citrate at room temperature is added to alcohol, oily drops are obtained but no crystals.¹ The water solution of triammonium citrate is alkaline to rosolic acid, thus fulfilling the prediction of Hildebrand.³ On exposure to the air a water solution of the salt loses ammonia and reacts acid.

Since the diammonium citrate is soluble in boiling alcohol, it is evident that the triammonium citrate salt that has become acid by loss of ammonia can be purified either by the removal of the diammonium citrate by extraction with boiling absolute alcohol or by passing through the finely powdered salts suspended in hot alcohol an excess of dry ammonia gas and working it up as in the original preparation.

Analyses.

The carbon, hydrogen and nitrogen content was determined by elementary analyses of a sample of the salt that had been dried in the steam oven for an hour and then dried further for some days over sulfuric acid in a desiccator.

I. 0.2501 g. of the salt gave: 0.1583 g. of H_2O and 0.2712 g. CO_2 ; calc. for $(NH_4)_3C_6H_5O_7$: H = 7.05, C = 29.61; found: 7.04 and 29.58.

II. 0.2115 g. of subst. gave 0.3660 g. of N; calc. for $(NH_4)_3C_6H_5O_7$: 17.28%; found: 17.30%.

III. Assuming that the salt was pure triammonium citrate an 0.1 N solution was made.

50 cc. of this solution = 0.4050 g. of the salt, gave on distillation with excess standard alkali 0.08513 g. of NH_3 . Calc. for $(NH_4)_3C_6H_5O_7$: 21.01%; found: 21.02.

¹ Heldt, *Loc. cit.*

² Van Itallie, *Ibid.*

³ Hildebrand, *Ibid.*

The excess of alkali in the distillation flask was determined and the citric acid content of the salt thus found. Calc. citric acid for $(\text{NH}_4)_3\text{C}_6\text{H}_5\text{O}_7$: 78.98%; found: 78.96.

For analysis and trial by a chemist in actual comparison with solutions used in the daily determination of phosphoric acid content of fertilizers, a sample of the salt analyzed above was sent to Dr. Paul Rudnick, Chicago. His report is given below:

"We made up a solution of ammonium citrate from the triammonium citrate which you sent us. The quantity received was a little more than sufficient for 500 cc. in all. Its reaction to azo-litmin, by the method described in my paper¹ 'On the Preparation of Neutral Ammonium Citrate,' was neutral. Analysis by a determination of both the NH_3 and citric acid content of the solution showed that the salt which you sent me must, therefore, have been 99.92% pure triammonium citrate. The specific gravity of this solution was 1.0898 at 20°. Accordingly, we added a sufficient amount of the salt to make the specific gravity 1.09 at 20°. The ratio between ammonia and citric acid was then that required by the Patten and Marti standard.²

"We then prepared a solution of neutral ammonium citrate from pure citric acid and ammonia and analyzed four different samples of fertilizers with each of the two solutions. The results obtained were as follows:

INSOLUBLE PHOSPHORIC ACID.

	Solution triammonium citrate. Per cent.	Official neutral ammonium citrate solution. Per cent.
10 and 5.....	0.74	0.71
Acid phosphate.....	0.10	0.10
Complete fertilizer containing acid phosphate only.....	2.29	2.27
Complete fertilizer containing acid phosphate and bone.....	4.55	4.58

"The concordance between these results is all that could be expected."

Dr. Rudnick's results corroborate fully those obtained in this and in other laboratories,³ the data of which it is unnecessary to give. The importance of this salt to the fertilizer chemist is manifest. His literature of recent years has been replete with easy, simple, and exact methods of preparing the "neutral ammonium citrate" solutions used in the determination of the insoluble phosphoric acid content of commercial fertilizers. While these valuable and interesting physical-chemical and analytical methods have in the main contributed somewhat to rendering more easy the preparation of this difficult solution, yet in no one method, or combination of these methods, has the solution of the problem been found. No two chemists have been able to prepare "neutral ammonium citrate solutions" that were in exact agreement one with the other as to their neutrality or their ammonia and citric acid content. It is hoped that the successful preparation of this salt, triammonium citrate, in a stable, workable form marks the beginning of the end of his troubles. It would

¹ Rudnick, *J. Ind. Eng. Chem.*, 5, 12, 998 (1913).

² Patten and Marti, *Ibid.*, 5, 567 (1913).

³ Grateful appreciation is hereby expressed to Dr. Rudnick and the others who have so kindly contributed to the success of this investigation.

seem so in view of the very evident fact that it is but necessary to weigh out, or add to water a sufficient amount of the salt to give the required specific gravity, and the solution is ready. The ease with which the solution can be prepared from the pure salt would preclude the necessity of making up large quantities of the solution so that deterioration by standing would be avoided. Uniformity in the results obtained in this very important analyses would thus be predicated upon uniformity of the ammonium citrate content of the solution. The difference in the hydrogen ion concentration of the normal and neutral solutions of ammonium citrate is so very slight¹ that the difference in the analytical results are negligible; and the ease and certainty of preparation of an accurate solution from the pure normal triammonium citrate salt would seem to predetermine the question in favor of the use of the triammonium citrate. Since, however, the neutral solution is prescribed legally as the solution to be used in the fertilizer analysis and since any change in the legal status would be dependent upon the report of chemists who have tried out the salt, this preliminary publication is made, although, as has been noted, the investigation of the triammonium citrate as contemplated and desired is still incomplete.

Summary.

Triammonium citrate can be obtained readily and easily as a stable compound by the passage of anhydrous ammonia gas into citric acid dissolved in an anhydrous solvent. The best solvent for this purpose is absolute alcohol heated to its boiling point. The yield of triammonium citrate is quantitative. Ninety-five per cent. alcohol may be used, but the yield is not quantitative.

The salt is a stable, crystalline substance. Analyses show it to have the composition represented by the formula $(\text{NH}_4)_3\text{C}_6\text{H}_5\text{O}_7$. It reacts alkaline to rosolic acid. It is exceedingly soluble in water and can not be recrystallized from its water solution. Precipitated, in the cold, from an aqueous solution by addition of alcohol an unstable crystalline form of the salt is obtained.

From practical tests in laboratories where daily analyses of fertilizers are made it has been shown that the salt lends itself readily to the making of solutions of 1.09 sp. gr. at 20°; that this solution of normal ammonium citrate gives, in parallel phosphoric acid determinations, results practically identical with the most carefully prepared "neutral" ammonium citrate solutions and can, therefore, well be substituted for the so-called neutral ammonium citrate solution.

STUDIES ON ENZYME ACTION. XII. THE ESTERASE AND LIPASE OF CASTOR BEANS.

By K. GEORGE FALK AND K. SUGIURA.

Received September 28, 1914.

In a former paper,¹ the results obtained in the extraction of a castor bean preparation by water and by solutions of different salts made it appear probable that substances showing different types of hydrolytic activity toward esters existed in castor beans. Greater activity, under certain fixed conditions, toward ethyl butyrate than toward triacetin was found associated with substances soluble in water, while greater activity toward triacetin than toward ethyl butyrate was found associated with a substance or with substances insoluble in water.

For the sake of a convenient terminology, the terms esterase and lipase will be used in this paper to represent these two types of hydrolytic action under certain definite conditions, esterase referring to the substance exhibiting the first action, lipase to the substance exhibiting the second. There is, however, no intention of establishing arbitrary differences between the two kinds of action. Undoubtedly the substance termed esterase hydrolyzes complex esters such as the fats, and the substance termed lipase hydrolyzes simple esters to a certain extent.

In this paper some experiments with the castor bean preparation on the activity toward triacetin in different salt solutions will be described; then the separation of the esterase and of a lipase from the castor bean preparation will be shown, together with a study of their hydrolytic actions under various conditions; and finally the analyses of the different preparations and the forms of combination of the nitrogen in them will be given.

In all of the tests of hydrolytic actions which are given in this paper, the procedure was the same as that described in preceding papers. When the action of a given preparation was measured on ethyl butyrate, one cc. of the neutral ester was added to the stated amount of solution or mixture, while if the action on triacetin was studied, 0.5 cc. of this ester, practically neutral in reaction, was used. The mixtures were placed in the incubator at 38–40° for 24 or 48 hrs. (or other time as stated) and then titrated with standard sodium hydroxide solution, approximately 0.1 *N*. At the same time, suitable blanks were run as usual and the final results, which alone are given here, give the corrected values for the acid formed from each ester, in terms of cc. of 0.1 *N* solution. The tests with ethyl butyrate are generally designated by Et Bu, with triacetin, by Triac.

The castor bean preparation used in these experiments was prepared

¹ IX paper of this series, *THIS JOURNAL*, 35, 1904 (1913).

from a new lot of cold pressed castor beans.¹ The shells were removed by hand, the kernels ground, extracted exhaustively with ether in a Soxhlet apparatus, dried in air and ground to pass through a 40 mesh sifter. Throughout this work, toluene was added to every solution and mixture, when extracting, filtering, or testing activities, to prevent bacterial growth.

A number of extraction experiments were carried out with the new preparation according to the method described in the IX Paper² with the former preparation.

The results showed, in agreement with the former work, that 70% of the material showing activity toward ethyl butyrate and 33% (50% in the former work) of the material showing activity toward triacetin, could be extracted by water.

Some tests of the activity of the preparation in sodium chloride and sodium sulfate solutions toward triacetin are of interest. With 0.2 g. castor bean preparation, 25 cc. solution, 0.5 cc. triacetin, and 24 hrs. tests, the following results were obtained:

TABLE I.—ACTION IN AQUEOUS SODIUM CHLORIDE AND SODIUM SULFATE SOLUTIONS OF CASTOR BEAN PREPARATION ON TRIACETIN.

	0.	0.02 M.	0.05 M.	0.1 M.	0.1 M.	0.5 M.	1 M.
NaCl.....	1.50	1.46	1.48	1.91	2.32	1.97	1.22
Na ₂ SO ₄	1.55	3.51	4.32

In the V Paper of this series³ it was shown that sodium chloride inhibited the action toward ethyl butyrate, the effect being distinct even at 0.005 *M* and increasing with increase in concentration of the sodium chloride. Toward triacetin the activity increased with increasing salt concentration to a maximum at about 0.2 *M* and then decreased again. These results are strikingly similar to those obtained with duodenal contents.⁴ These showed in a series of tests with water and with 0.1 *M* sodium chloride solution that the presence of the salt inhibited markedly the action toward ethyl butyrate in every case, but that toward triacetin either very slight inhibition or marked acceleration was shown. The probable presence of an esterase and a lipase in intestinal contents under different conditions was described in the tenth paper. It would appear from these results, that the esterase and the lipase present are affected differently by the salts, the action of the esterase being inhibited by the simple uni-univalent salts at all concentrations, that of the lipase being accelerated at certain concentrations and inhibited at other, higher, concentrations.

³ THIS JOURNAL, 35, 601 (1913).

⁴ X paper of this series, THIS JOURNAL, 36, 1054 (1914). Cf. also the work of Terroine (*Biochem. Z.*, 23, 404 (1910)) with animal pancreatic juice.

Sodium sulfate exerted no apparent action on the activity of the castor bean preparation toward ethyl butyrate, but exerted marked acceleration toward triacetin. It is possible that here a retarding action of the sodium and accelerating action of the SO_4 on the two enzymes exert their influences to produce the results observed.

The effect of drying and of heat on the activity of the ether extracted, air dried castor bean preparation was studied. The preparation was placed in a vacuum desiccator containing calcium chloride or phosphorus pentoxide for the required lengths of time, the loss in weight determined and the activity of 0.18 g. portions tested toward ethyl butyrate and triacetin in 25 cc. H_2O for 24 hrs. at $38-40^\circ$. Other portions were heated and tested similarly, and finally some portions were first dried in desiccators, then heated, and finally tested. The results are given in Table II.

TABLE II.—ACTION OF DRYING AND OF HEAT ON THE LIPOLYTIC ACTIVITY OF THE CASTOR BEAN PREPARATION.

Treatment.	Grams taken.	Loss. Gram.	Loss. Per cent.	Activity.	
				Et Bu.	Triac.
CaCl_2 desiccator, 3 days.....	1.0034	0.0719	7.17	1.59	1.56
P_2O_5 desiccator, 2 days.....	1.0074	0.1055	10.47
1 day more.....	..	0.1067	10.59	1.70	1.70
$100-110^\circ$, 3 hrs.....	1.0211	0.0930	9.11	0.31	0.61
100° , to constant weight.....	2.5048	0.2573	10.27	0.68	0.95
CaCl_2 desiccator, 2 days.....	1.0299	0.0667	6.47
2 days more.....	..	0.0719	6.98
Then $100-110^\circ$, 3 hrs.....	..	0.0988	9.59	0.13	0.41
P_2O_5 desiccator, 3 days.....	1.0033	0.1022	10.19
Then $100-110^\circ$, 3 hrs.....	..	0.1038	10.34	0.28	0.64

The activity of the preparation did not decrease on drying in a vacuum desiccator over calcium chloride or phosphorus pentoxide. With the latter, considerably more moisture was taken out than with the former, as was to have been expected. On heating to $100-110^\circ$, although the loss in weight was not as great as in standing over phosphorus pentoxide, the activity was decreased very much. Also, first drying over calcium chloride to remove most of the moisture and then heating decreased the activity similarly. Drying over phosphorus pentoxide to remove practically all the moisture, and then heating, by which only 0.15% more was lost, decreased the activity just as much as if no preliminary drying had taken place. These results indicate that the inactivation due to heating the lipase is not connected with a simple loss of water or dehydration, but is doubtless due to some more deepseated chemical change.

The analysis of the castor bean preparation may be given here. The methods of analysis used were briefly as follows: Total ash was determined by careful heating and subsequent ignition of the material in a platinum dish, moistening with nitric acid and reignition until the ash

was no longer dark colored. The residue was taken up with water and nitric acid, calcium sulfate precipitated by sulfuric acid and alcohol, and, in the filtrate from this precipitate magnesium and phosphorus were determined in separate aliquot parts, each as magnesium pyrophosphate.¹ The analyses by the Neumann method were carried out by heating the material with concentrated sulfuric acid and addition of concentrated nitric acid until the mixture was colorless. After dilution, the calcium and magnesium were determined in the usual way, the phosphorus by precipitation with molybdate solution and weighing the precipitate $(\text{NH}_4)_3\text{PO}_4 \cdot 12\text{MoO}_3$ after drying at $110-120^\circ$ in a Gooch crucible.

Castor Bean Preparation.—9.70% moisture ($100-110^\circ$), 11.6% N (Kjeldahl), 6.70% ash, 4.13% P_2O_5 , 1.42% MgO , 0.16% CaO (Neumann method).

7.42% ash in dry substance.

13.9% N in ash- and moisture-free substance.

Esterase Material: Preparation and Properties.

In extracting the castor bean preparation with water it was found best to use a large number of small portions instead of few portions and large amounts of material. The extraction was more satisfactory in this method of working, more homogeneous mixtures were obtained and the filtration through asbestos was much more rapid. In the following work, which was carried on from the preparative standpoint, 0.5 g. preparation and 60 cc. water were used in each portion, and the extraction allowed to proceed for 24 hrs. since this length of time appeared to be sufficient to remove most, if not all, of the esterase. It was also found more convenient to centrifuge the extraction mixtures before filtering through asbestos, although this procedure was not essential.

The clear aqueous extracts contained the esterase or material with which the esterase was associated. 25 cc. of the extract required 0.20 cc. 0.1 N NaOH solution to be neutral toward phenolphthalein. Saturating the extract with $(\text{NH}_4)_2\text{SO}_4$ produced a flocculent precipitate, which, when dried on a porous plate, showed a small but appreciable activity, greater toward ethyl butyrate than toward triacetin under the standard conditions used. Owing to the presence of adsorbed ammonium sulfate, these titrations with alkali were carried out after the addition of neutralized formaldehyde solution. Precipitation of the aqueous extracts with other salts such as NaF, NaCl, MgSO_4 , or HgCl_2 gave either small amounts of inactive material or turbidities which could not be filtered. The addition of alcohol or of acetone to these solutions also produced marked turbidities from which, however, no solid material could be obtained either by centrifuging or by filtration.

Active solid preparations containing the esterase could be obtained by first dialyzing the clear aqueous extracts from the castor bean preparation

¹ Cf. Abderhalden, *Handbuch der bioch. Arbeitsmeth.*, Grotz (1912).

before attempting precipitation. These clear extracts became very turbid on dialysis and small amounts of solid matter separated. At the same time they became very nearly neutral in reaction toward phenolphthalein. The volume of the solutions increased 8-10% on 24 hrs. dialysis against running water in collodion bags. The activity of the neutral turbid dialyzed solution was less than that of the slightly acid undialyzed extract, but the addition of the amount of acetic acid to the former necessary to produce the same acidity as the latter resulted in very nearly the same activity. The turbid dialyzed solutions could also be filtered and the clear solutions showed the same activity as the turbid. To obtain these clear filtrates, the turbid solutions must be passed repeatedly through hardened filter paper. The following tests of the activities of these solutions and mixtures may be cited in this connection:

Clear aqueous extracts.—Tested 25 cc. portions (acidity equivalent to 0.20 cc. 0.1 *N* NaOH), 24 hrs. Et Bu 1.23; Triac. 0.48.

Dialyzed this clear extract 18 hrs.—Very turbid. Tested 25 cc. portions (acidity equivalent to 0.08 cc. 0.1 *N* NaOH) after the addition of 0.12 cc. 0.1016 *N* acetic acid. Et Bu 1.06; Triac. 0.35.

Filtered the turbid dialyzed extract until clear.—Tested 25 cc. portions (acidity equivalent to 0.08 cc. 0.1 *N* NaOH) after the addition of 0.12 cc. 0.1016 *N* acetic acid. Et Bu 0.91; Triac. 0.18.

Clear aqueous extract.—Tested 25 cc. portions (acidity equivalent to 0.20 cc. 0.1 *N* NaOH), 24 hrs. Et Bu 1.05; Triac. 0.56.

Dialyzed 16 hrs., volume increased 8%.—Very turbid. Neutral. Tested 25 cc. portions. Et Bu 0.53; Triac. 0.25. Tested 30 cc. portions after addition of 0.20 cc. 0.1016 *N* acetic acid. Et Bu 0.96; Triac. 0.33.

Filtered dialyzed solutions till clear.—Tested 25 cc. portions. Et Bu 0.53; Triac. 0.24.

These results show clearly that the active esterase was contained in the clear neutral solution obtained after dialyzing and filtering the aqueous extracts of the castor bean preparation. The presence of small amounts of acid increased the activity of the esterase considerably, but its action was still very marked even without this added acid. The addition of dilute Ba(OH)₂ solution to the turbid dialyzed solution until it was strongly alkaline cleared up the turbidity to a great extent. This appears to eliminate any appreciable quantities of phytin as one of the constituents of the solution.

The effect of dialyzing the clear aqueous extracts of the castor bean preparation for different lengths of time was studied in so far as any action was noticeable on the activity of the solutions. In Table III, the first column indicates the lengths of time the clear extracts of the castor bean preparation were dialyzed in collodion bags against running water having a temperature between 10° and 15°. The second and third columns show the volumes of the solutions before and after dialysis. The fourth column gives the volumes of the solutions used in making the activity tests. These

tests were made after filtering the turbid dialyzed solutions. The last four columns give the results of the activity tests made directly without the addition of acid. Under "Found" are given the results actually obtained, under "Cor." are given the results calculated from those "Found," to 25 cc. of original undialyzed solution. These corrected results give a truer measure of comparative activities. The analyses of the solid preparations obtained from these solutions will be given in Table IV in connection with some other analyses.

TABLE III.—THE EFFECT OF DIALYSIS ON THE ACTIVITY OF THE ESTERASE.

Time of dialysis. Hrs.	Volume.		Cc. used for activity tests.	Activities, 24 hrs.			
	Before dialysis. Cc.	After dialysis. Cc.		Et Bu.		Triac.	
				Found.	Cor.	Found.	Cor.
5	1150	1200	25	0.77	0.80	0.27	0.28
18	350	375	25	0.73	0.78	0.24	0.26
20	900	960	25	0.59	0.63	0.29	0.31
66	650	720	25	0.44	0.49	0.18	0.20
90	900	1000	25	0.34	0.38	0.12	0.13
93	800	840	25	0.33	0.35	0.23	0.24

These results show that the activity of the esterase decreased on continued dialysis, these decreases being very nearly proportional to the times of dialysis.

The turbid dialyzed solution precipitated with alcohol gave a solid preparation which showed no activity. Precipitation with three volumes of acetone, standing over night, filtering, grinding repeatedly with fresh acetone, and drying in a vacuum desiccator gave active preparations. Some tests with these preparations, called E_I for convenience, follow:

0.1 g. E_I , 50 cc. water, 0.50 cc. 0.1016 <i>N</i> acetic acid, 48 hours' test; Et Bu 1.40.							
0.02 g. E_I , 50 cc. H_2O , 48 hours' test; different amounts 0.1016 <i>N</i> acetic acid.							
cc. 0.1016 <i>N</i> acetic acid.....	0	0.10	0.20	0.30	0.40	0.50	
Activity toward Et Bu.....	0.10	0.20	0.18	0.19	0.18	0.14	

An esterase preparation, E_{II} , was prepared from the clear filtrate from the turbid dialyzed extract similarly by precipitation with acetone, filtering, grinding with fresh acetone and drying in a vacuum desiccator.

The activity of E_{II} is shown by the following result: 0.05 g. E_{II} , 25 cc. water, 0.20 cc. 0.1016 *N* acetic acid, 24 hours' test; Et Bu 0.53, Triac. 0.13.

In preparing E_{II} , it was found that, using apparently the same procedure and manipulation, at times solid material was obtained showing no activity. The reasons for these differences are entirely unknown.

Attempts to prepare purer material by dissolving E_I or E_{II} in water, filtering, dialyzing, filtering again, and precipitating with acetone gave solid preparations showing only small activity toward ethyl butyrate.

The castor bean preparation gave strong reactions for tyrosine (Folin's reagent¹), tryptophane (Hopkins-Cole test), aromatic group (Xantho-

¹ *J. Biol. Chem.*, **12**, 239 (1912).

proteic test) and carbohydrates (Molisch test). 5-10 mg. substance were used in these and the following tests. The esterase preparations E_I and E_{II} gave negative tests for carbohydrates, positive tests for tryptophane and aromatic groups, and very faintly positive for tyrosine. The redissolved and reprecipitated E_I preparation gave negative tests for tyrosine and tryptophane, otherwise no change.

The results obtained in determining moisture, ash, and P_2O_5 , in the different esterase preparations are given in Table IV.

TABLE IV.—ANALYSES OF ESTERASE PREPARATIONS.

Preparation.	% loss in 3 hrs. at 100-110°.	% ni- trogen.	% ash.	% P_2O_5 .	% ash in dried subst.	% nitrogen in ash and moisture-free substance.
E_I	8.55	12.8	8.03	3.85	8.78	14.4
E_{II} (5 hrs. dialysis)	6.56	13.9	4.80	2.08	5.14	15.7
E_{II} (20 hrs. dialysis)	8.38	14.2	4.26	1.43	4.65	16.3
E_{II} (66 hrs. dialysis)	7.52	14.0	4.70	..	5.08	15.9
E_{II} (90 hrs. dialysis)	7.80	13.5	4.62	0.85	5.00	15.4
E_I (reprecipitated)	7.37	15.2	1.26	0.08	1.36	16.6

The amount of nitrogen in the esterase preparations was considerably greater than in the original castor bean preparation, while the percentage of ash was less, except for E_I . The percentage of nitrogen and the absence of carbohydrate reaction indicate that the preparation is mainly, if not entirely, protein in nature. The length of time of dialysis exerted no influence on the percentage of ash present, while with the nitrogen the differences in the different preparations showed no regularities and were probably accidental. The preparation E_I , obtained by precipitating the turbid dialyzed extract, contained more ash and less nitrogen than did the preparation E_{II} obtained by precipitating the clear filtered dialyzed extract. The reprecipitated preparation showed less ash and more nitrogen than did any of the others, but this preparation was only slightly active. The only regularity between the activity and the composition appeared to be in the percentage of P_2O_5 present. For the series E_{II} and times of dialysis and including the reprecipitated E_I , the greater the activity, the more P_2O_5 was present.

The existence of the water soluble esterase in castor beans is of interest in connection with some work on the hydrolysis of organic phosphorus compounds by enzymes published recently by R. H. A. Plimmer.¹ Plimmer found that the enzyme glycerophosphatase, capable of hydrolyzing glycerophosphoric acid into glycerin and phosphoric acid, was present in extracts of intestinal mucosa, kidney, castor oil seeds, yeast, and bran, but not in pancreas or liver extracts. He considered that "the absence of the enzyme from the extracts of pancreas and liver, which were prepared specially for lipase, and the presence of the enzymes in the extracts of the intestine

¹ *Biochem. J.*, 7, 43 (1913).

and kidney, tissues not usually regarded as good sources of lipase, point to this enzyme being distinct from lipase. Proof of the difference of the enzymes is given by the experiment with castor oil seeds; lipase is insoluble in water but an aqueous solution contains glycerophosphatase." As far as castor beans are concerned, the work described in this paper shows a soluble esterase to be present in them. In the course of this work, intestinal secretions and pancreatic juice and bile were tested for ester-splitting enzymes, and it is significant that it was made extremely probable in the X Paper that an esterase existed in intestinal juice and a lipase in pancreatic juice and bile. Although the evidence is not direct or complete, it is likely that the esterase and glycerophosphatase, if not identical, exist together and may be detected in preparations from the same sources.

Lipase Material: Preparation and Properties.

The residues of the castor bean preparation, after extracting with water, contained the greater part of the lipase, active toward triacetin. Evidence obtained in the extraction experiments indicated that the water-insoluble lipase was somewhat soluble in sodium chloride solutions.¹ Some preliminary experiments on the water-insoluble lipase material with different salt solutions showed that sodium chloride was the most satisfactory salt to use and the further experiments were, therefore, carried out exclusively with it.

A number of extraction experiments with sodium chloride solutions of different concentrations were made. The results are given in Table V. The water-soluble esterase was first removed by extraction as described. The residues from these extractions were then combined and treated with the requisite sodium chloride solution in the ratio of residues corresponding to one gram original castor bean preparation to 100 cc. salt solution. These were allowed to extract 24 hrs. at room temp., filtered clear through asbestos with suction, and the filtrates dialyzed 18 to 20 hrs. against running water in collodion bags. White precipitates formed in the solutions in the bags as the salt was removed by dialysis. The removal of the sodium chloride was almost always complete in 18 hrs. The volumes of the solutions increased as a rule. After dialysis, aliquot portions of the mixtures (solutions + precipitates) were tested for activity in the usual way. Practically no activity toward ethyl butyrate was found for any of the mixtures. With the triacetin tests, the activities found for the mixtures after dialysis were calculated for purposes of comparison to correspond to the amount of extracting solution obtained from the extraction of 0.2 g. original castor bean preparation.

A number of sets of such experiments were carried out. In place of giving the details of these, only the mean values for the different concen-

¹ IX paper of this series, *Loc. cit.*, p. 1913.

trations of salt solutions used will be given. The first row of Table V shows the concentration of salt solution; the second, the activity, multiplied by 100, toward triacetin of the dialyzed mixture corresponding to 0.2 g. castor bean preparation; and the third row the results taken from the smoothed curve obtained by plotting concentration of extracting salt solution against the observed activities of the mixtures, as given in the first and second rows.

Activity from curve.....	38	40	39	38	35	32	29	24	14

These results show that 1.5 *N* NaCl solution extracted more active lipase than did any other concentration. In every salt extraction the removal of the salt by dialysis produced a precipitate in the solution. These mixtures, the activities of which were given in Table V, could be filtered readily. The filtrates showed no activity toward triacetin. The solid material must, therefore, contain the active lipase.

In the further work with this lipase, two extracting solutions were used; a saturated salt solution, giving the largest quantity of solid, the material obtained being designated *L*_I; and a 1.5 *N* salt solution, giving the most active extract, the material thus obtained being designated *L*_{II}.

The castor bean residues after water and repeated salt extractions still showed marked activity toward triacetin, but very little toward ethyl butyrate. The continued treatment of the castor bean preparation with water and especially with salt solution undoubtedly modified the properties of some of the substances, colloidal and other, present originally in the preparation. The fact that the residues after the extractions described still show such marked activity, indicates that one or more other lipases are present which could not be obtained by the simple extractions described.

The effect of varying the times of dialysis of the salt extractions on the activity of the resulting mixtures was studied.

It was found that the activity of the lipase mixture was not diminished appreciably even after dialyzing continuously for six days. This behavior was in marked contrast to that of the esterase, the activity of which diminished fairly rapidly on continued dialysis. The difference in physical properties may account in part for this; the esterase remained in solution, while the lipase was precipitated out as the salt was removed and remained suspended in the solution.

A number of attempts made to obtain the solid enzyme L_I in active form from the dialyzed mixtures of the saturated salt solution failed.

More extended experiments were made with the L_{II} mixture as obtained by dialyzing the 1.5 N salt extractions. First the activity of mixtures in water and in the salt solutions, suspended and dissolved, were compared. 800 cc. of 1.5 N salt extract were divided into two parts. 400 cc. were dialyzed for 48 hrs. against running water. The salt was removed completely and the volume increased to 565 cc. 50 cc. tested for 24 hrs. gave an activity of 0.62 toward triacetin. The remaining 400 cc. of the extract were allowed to stand at room temperature 48 hrs., the volume brought to 565 cc. with 1.5 N salt solution, 50 cc. portions tested for 24 hrs., giving an activity of 0.56 toward triacetin. Whether the material was dissolved in the salt solution or suspended in the aqueous solution appeared to be of small influence on its hydrolyzing action.

The L_{II} solution mixture after being dialyzed, filtered, the residue washed thoroughly with water, and taken up with fresh water, showed very marked lipolytic action, indicating that the dialyzed solution contained no essential constituent (such as a coenzyme) of the lipase, but that the activity was all concentrated in the solid material L_{II} .

A number of tests with 50 cc. L_{II} water mixtures, 24 hrs., with added salts were made:

	H_2O .	0.1 M NaCl.	0.05 M NaF.	0.05 M $MgSO_4$.	0.002 M $MnSO_4$.
Et Bu activity....	0.11	0.09	0.08	0.10	0.09
Triac. activity....	0.92	0.95	0.48	0.89	0.97

The only marked influence of the salts was shown by the sodium fluoride, which inhibited the action strongly. The lack of either retarding or accelerating action of the sodium chloride is of interest, as well as the lack of accelerating action of the magnesium sulfate. Series of experiments in which the amount of water and the amount of triacetin were varied were also carried out. In the following experiments, different quantities of the L_{II} -water mixture and water were tested with 0.5 cc. triacetin for 24 hrs.:

Cc. L_{II} -water mixture.....	10	20	40	60	10	10	10
Cc. water added.....	0	0	0	0	10	30	50
Activity.....	0.40	0.90	1.59	1.97	0.41	0.37	0.30

Except for the largest amount of L_{II} -water mixture used, the action was approximately proportional to the quantity of the L_{II} present. Similarly for the same amount of L_{II} -water mixture, addition of water exerted no influence on the reaction except for the largest quantity of water added.

With 50 cc. L_{II} -water mixture and different amounts of triacetin, 24 hrs. tests gave the following results:

Cc. triacetin.....	0.1	0.2	0.3	0.5	0.8	1.0	1.5	2.0
Activity.....	0.46	0.59	0.66	0.73	0.75	0.77	0.73	0.77

After a certain amount of triacetin, addition of still more did not increase the amount of action with the given quantity of lipase. The results of the last two series indicate that a definite quantity of lipase can only react with a certain quantity of triacetin in a given time. 0.5 cc. triacetin is the maximum amount with which 50 cc. L_{II} -mixture could react, so that the result with 60 cc. L_{II} -mixture in the previous series was not proportional to the less amounts of lipase, because in the latter case an excess of triacetin was present, in the former, insufficient triacetin.

The precipitated L_{II} in the mixtures was readily dissolved by small amounts of dilute hydrochloric acid, sodium hydroxide, or glacial acetic acid, but not dilute acetic acid.

The solid L_{II} material was prepared by filtering the precipitate from the dialyzed solutions on hardened paper, grinding with acetone in a mortar for some time and finally drying in a vacuum desiccator. The white powder obtained in this way was, however, only slightly active. The addition of small amounts of acetic acid or of sodium hydroxide did not increase the activity. This behavior is in marked contrast to that of the esterase which could be obtained active in solid form readily.

An attempt was made to obtain a more homogeneous material from the L_{II} , if possible. Two grams of L_{II} were treated with 100 cc. 1.5 *N* sodium chloride solution. After ten minutes, when most of the solid had gone into solution, the mixture was filtered through hardened paper, the opalescent filtrate dialyzed against running water 20 hrs., a heavy white precipitate forming and the volume increasing to 300 cc. Practically no activity was shown by the mixture.

The analyses of the lipase preparations are given in Table VI.

TABLE VI.—ANALYSES OF LIPASE PREPARATIONS.

Preparation.	% Loss in 3 hrs. at 100–110°.	% Ni- trogen.	% Ash.	% P_2O_5 .	% Ash in dried subst.	% Nitrogen in ash and mois- ture-free substance.
L_I	9.76	14.3	6.29	3.93	6.95	17.0
L_{II} (24 hrs. dialysis).....	6.57	15.1	4.04	.50	4.32	16.9
L_{II} (44 hrs. dialysis).....	5.37	15.3	3.96	.54	4.19	16.9
L_{II} (67 hrs. dialysis).....	6.96	15.0	3.89	.76	4.18	16.8
L_{II} (92 hrs. dialysis).....	8.26	14.1	5.71	.77	6.22	16.4
L_{II} (115 hrs. dialysis).....	8.00	14.5	4.80	.85	5.22	16.6
L_{II} (141 hrs. dialysis).....	7.00	15.1	3.60	.14	3.87	16.9
L_{II} (reprecipitated).....	7.59	16.1	0.70	0.20	0.76	17.6

The length of time of dialysis exerted no effect on the composition of the lipase preparation. The percentage of ash varied irregularly and is doubtless due to accidental causes. The only distinct features of the analyses are the facts that L_I , obtained with saturated salt solution, con-

tained most ash, and that the redissolved and reprecipitated L_{II} preparation contained less ash and more nitrogen than any of the other preparations.

Both the L_I and L_{II} preparations gave negative tests for carbohydrates (Molisch test) faintly positive for tyrosine (Folin reagent), distinctly positive for tryptophane (Hopkins-Cole test) and strongly positive for aromatic groups (Xanthoproteic test).

A characteristic property of the esterase of castor beans is its solubility in water, and of the lipase, its insolubility in water and solubility in salt solution. The hydrolytic power of these enzymes is doubtless associated with certain groups in the (presumably) protein molecule, and it is readily conceivable that these same groups might be present in protein molecules showing solubilities different than those of the castor bean preparation. It will be shown in a future paper, that the lipase of soy beans, which shows chemical properties similar in many respects to those of the lipase of castor beans, can be obtained dissolved in clear aqueous solution.

Chemical Nature of Preparations.

The principal forms in which nitrogen was present in the different preparations described in this paper were determined by Van Slyke's method.¹ The microapparatus² was used. About one gram of substance was hydrolyzed in each analysis. The final results are given in Table VII. The first set of results is for the castor bean preparation, the second for the esterase preparation E_I , the third for the lipase preparation L_I , the fourth for the lipase preparation L_{II} .

TABLE VII.—FORMS OF NITROGEN IN PREPARATIONS EXPRESSED AS PERCENTAGES OF TOTAL NITROGEN.

	Castor bean preparation.	Esterase E_I .	Lipase L_I .	Lipase L_{II} .

Non-amino nitrogen of filtrate.....	...	3.9	...	1.5
Totals.....	103.1	101.7	103.8	101.9

In carrying out the hydrolyses by heating with 20% hydrochloric acid as recommended by Van Slyke, it was observed that with the solid preparations, the substances were charred rapidly and separated considerable quantities of black carbonized material. An analysis was, therefore,

¹ *J. Biol. Chem.*, 10, 15 (1911); 12, 275 (1912).

² *Ibid.*, 16, 121 (1913).

made of an L_{II} -water mixture which had shown marked lipolytic action. Heating this mixture with the hydrochloric acid in the customary way resulted in a gradual darkening of the solution and deposition of very little black material. The results of this analysis are given in the column headed Lipase L_{II} . The preparation of the solid L_{II} from the L_{II} mixture involved treatment with acetone and was accompanied by the inactivation of the material. It is possible that some chemical change was brought about in this treatment which manifested itself in the different behavior of the preparations on treating with hydrochloric acid, although no clew as to the nature of this change is evident at present.

Very little difference is shown in the relative proportions of the forms of nitrogen in the castor bean, esterase and lipase preparations. The nitrogen content of the ash-free esterase preparation E_{II} (15.4 to 16.3%) and of the ash-free lipase preparation L_{II} (16.4 to 16.9%) indicate that these consisted mainly, if not entirely, of protein material. The nitrogen distribution results confirm this conclusion in so far as it is shown that the forms in which the nitrogen exists in them are the same as those in which the nitrogen exists in other typical proteins, with differences in the amounts present in the different forms. The absence of carbohydrate substances (negative Molisch test), and of fats (method of preparation), also bears out the view that the preparations are essentially protein.

Sherman and Gettler¹ have furnished fairly conclusive proof that their amylase preparations, obtained in a high state of purity and in very active form, were essentially protein in character. Every enzyme must naturally be considered independently as far as its chemical constitution is concerned, but it is a significant fact that up to the present time, protein material has been found in every enzyme preparation which has been investigated carefully and purified as far as possible. The amounts of protein found vary greatly. The invertase preparations of Nelson and Born,² which appear to represent the products of greatest purity for this enzyme obtained up to the present, showed an average nitrogen content of about 1.3%, while at the other extreme are the amylase preparations of Sherman and Gettler and the esterase and lipase preparations described here which appear to be entirely protein in character.

In considering whether the protein itself, or some part of it, can produce reactions which are characteristic of enzymes, it has been found possible to go somewhat further with the lipolytic actions than with the actions caused by other enzymes. Work in this laboratory has shown³ that simple aminoacids not only exert hydrolytic actions on esters, but that relatively

¹ THIS JOURNAL, 36, 1790 (1913).

² *Ibid.*, 36, 396 (1914).

³ II paper of this series, THIS JOURNAL, 34, 828 (1912); M. L. Hamlin, VII and VIII Papers, *Ibid.*, 35, 624, 1897 (1913).

simple differences in the structures of aminoacids caused changes in the rates of hydrolyses of simple esters not dependent upon the hydrogen ion concentration alone; in other words, that they act selectively on the esters. These actions, it is true, are comparatively small, but, if simple aminoacids can be shown to duplicate, even to less degree, the actions of different lipases, it is not only possible, but probable, that groupings in complex proteins exist and may be found which will account for the enzymatic changes. There is no direct evidence that such groupings are the active factors, but the indirect evidence shows that the existence of such groupings is probable and would be sufficient to account for the reactions.

The writers wish to thank Mr. Morris Erenstoft for his efficient aid in carrying out the experimental work described in this paper.

Summary.

The extraction results described in a former paper were confirmed with a new castor bean preparation.

The action of the castor bean preparation on triacetin in the presence of some neutral salts was described. The activity of the preparation was tested after drying and heating under different conditions.

An esterase preparation, active toward ethyl butyrate, was separated by extraction with water, and its properties studied in solution and in the solid form. Its probable identity with glycerophosphatase was suggested.

A lipase preparation, active toward triacetin, was separated by extraction with 1.5 *N* sodium chloride solution, and its properties studied.

The forms of combination of the nitrogen in the preparations were determined. The probable protein nature of the esterase and lipase was discussed.

NEW YORK, N. Y.

THE TOTAL AMINO NITROGEN IN THE SEEDLINGS OF THE ALASKA PEA.

By THOS. G. THOMPSON.¹

Received October 24, 1914.

While considerable attention appears to have been devoted to the occurrence of asparagin in plants, very little study seems to have been given to the total amount of amino and amide nitrogen that exists in plants at various stages of growth. Schulze² published his ideas concerning the formation of amino acids in plants in 1898. Later Scruti³ pointed out the importance played by phosphorus in the formation of acid amides and amino acids which go to build up the protein molecules. It is a gener-

¹ Acknowledgment is made to Dr. G. F. White who suggested and supervised this research.

³ *Staz. sper. agrag. Ital.*, 41, 456.

ally accepted fact that the existence of these nitrogenous compounds is a result both of the decomposition of the plant proteins and of synthetic processes. The exact steps of the syntheses are not definitely known. Franzen¹ has worked out a long series of reactions explaining, from a purely theoretical standpoint, the synthetic formation of the amino acids and the acid amides. His assumptions are based entirely upon the theory of Treub, in that the formaldehyde unites with the ammonia and the hydrocyanic acid to form the amino nitriles, which are later subjected to hydrolysis. The formaldehyde is formed by the reduction of the carbonic acid, and the ammonia and hydrocyanic acid are considered as the reduction products of the nitrates. From the theoretical explanation of Franzen and the experimental work of several investigators, it is concluded that the nitrogenous matter in the plants is constantly undergoing changes. Thus the percentage of the amino nitrogen should vary at different stages in the growth of the plant.

In 1890, Frank called attention to the fact that the leaves of plants contain more asparagin in the evening than in the morning. Kiesel² much later made a study of the changes undergone by the nitrogenous matter in *Trifolium Pratense Rept.* When the plants were kept in the dark he was able to demonstrate the presence of a small amount of arginine and showed the absence of other hexone bases. In the fresh plants, those that had been influenced by the action of sunlight, he was able to detect slight traces of amino valeric acid and leucine with more or less certainty. Upon keeping the plants in the dark for some time, however, enough leucine was present so that it was identified without any difficulty.

Andre³ studied the percentage of amino and amide nitrogen in the nitrogenous materials found in the leaves of plants at different stages of their growth during the year. The leaves in active life, during the months from May to October, upon subjection to analysis, indicated that the total nitrogen (dry material) decreased from 3.4% to 1.8%, while the amino nitrogen at first decreased from 0.53% in May to 0.10% in July, and then gradually increased again to 0.48% in October. As the result of his work, he concludes that the elaboration of the amide nitrogen may be considered uniform throughout the life of the leaf, with the exception of the period of fertilization of the flowers. At this period, translocation of the nitrogenous matter in the plant became very marked.

Experimental.

This investigation was undertaken to obtain some systematic data concerning the relation of the total nitrogen to the amino nitrogen in the grow-

¹ *Chem. Zentr.*, 1910, II, 983.

² *Z. physiol. Chem.*, 49, 72-80 (1906).

³ *Compt. rend.*, 148, 1685-1687.

ing plant, applying a method for the determination of the amino nitrogen which would prove to be, at the same time, both accurate and simple. The method used in the determination of the amino nitrogen in this research consists in the measurement of the nitrogen evolved according to the general reaction:

This reaction was permitted to take place in the apparatus recommended and fully described by D. D. Van Slyke¹ for the determination of small percentages of amino nitrogen. This apparatus was utilized exclusively in obtaining the percentages given below. In brief, it consists of a deaminizing vessel which is connected with a buret of 2 cc. capacity and a tube through which acetic acid and sodium nitrite are permitted to flow into the deaminizing vessel. A small buret is used to introduce the required amount of sample, containing the amino acids, into contact with the solution of the nitrous acid. The deaminizing portion of the apparatus is also connected to a gas buret that is graduated to 0.02 cc. This in turn is joined to a Hempel pipet containing an alkaline solution of potassium permanganate for the absorption of the nitric oxide, which is liberated in considerable quantities during the reaction. The detailed manipulation of the apparatus is completely described by Van Slyke in both of his papers. The modified form of the apparatus was used in making all the analyses reported in this paper.

For the purpose of determining the total nitrogen present in the seedlings, the standard Kjeldahl method was utilized.

In running blank determinations with the amino apparatus, a small volume of gas that was not absorbed by the alkaline potassium permanganate was obtained on using sodium nitrite that had been permitted to stand for a day and then filtered from the slight amount of sediment. After running a number of blank determinations and securing their readings it was found that a correction of 0.188 mg. of nitrogen would have to be made. On the other hand, if sodium nitrite was employed that had not been filtered, it was found that a greater amount of gas remained unabsorbed, and thus a correction of 0.199 mg. of nitrogen would be necessary in the regular determinations. In all the experimental work given in this paper, only the filtered sodium nitrite was employed.

From one and a half to five grams of the samples of the seedlings, or different portions of the plant for analysis, were weighed out, transferred and ground finely in a mortar. Water was then added to dissolve the amino acids that were present. As some of the proteins are more or less soluble in water, a drop of glacial acetic acid was introduced into the solution in order to precipitate those that might be present. The solutions were made up in graduated flasks of 25 cc., 50 cc., or 100 cc. capacity,

¹ *J. Biochem.*, 9, 185 (1911); 12, 275-284 (1912).

depending upon the size of the sample taken for analysis. Before running into the small buret, attached to the deaminizing vessel, the solutions were carefully filtered.

The formation and distribution of the amino acids and the acid amides in the Alaska pea were studied, special attention being given to its occurrence in the very young plants or seedlings. All the specimens for analysis were grown in a rich, moist soil and in a room of moderate temperature with full advantages for securing the rays of the sun. Every twenty-four hours a few of the seedlings were removed from the soil and, after removing all the earthy particles carefully with the aid of a soft brush, subjected to analysis. This was done for seven consecutive days with the following results:

TABLE I.

	Natural.		Dry material		Amino N, Total N Per cent.
	Total nitrogen. Per cent.	Amino nitrogen. Per cent.	Total nitrogen. Per cent.	Amino nitrogen. Per cent.	
1-Day seedlings.....	1.75	0.115	3.27	0.215	6.58
2-Day seedlings.....	1.51	0.124	3.22	0.265	8.23
3-Day seedlings.....	1.47	0.151	3.28	0.337	10.52
4-Day seedlings.....	1.42	0.164	3.35	0.386	11.52
5-Day seedlings.....	1.067	0.197	3.44	0.635	18.46
6-Day seedlings.....	0.997	0.214	3.48	0.747	21.46
7-Day seedlings.....	0.934	0.262	3.53	0.998	28.27

The original seed contained 0.088% of amino nitrogen.

In all cases, samples of the fresh plant were used for the exact estimation of both the total and the amino nitrogen. A third sample, for the determination of moisture, was always weighed out and dried in a closet at the temperature of boiling water for five or six hours. From the results given above, it is seen that there is a steady increase in the percentage of the amino nitrogen and that there is a marked increase in the occurrence of the amino nitrogen in the first- and the fifth-day seedlings. This increase in the first-day seedling is due, undoubtedly, to the decomposition of the proteins present in the original seed and indicates the formation of the food supply for the new protein material. The one-, two- and three-day seedlings all maintained the shape of the seed, but were, of course, much larger in size. The four-day seedling contained a small plumule, while the five-day seedling took the form of a regular plant. The plumules and roots of the six- and seven-day seedlings were larger and showed more signs of development. The large increase in the percentage of amino nitrogen in the five-day plant is probably explained by the rapid transformation of the seed and thus the requirement for a greater quantity of plant food of this nature to build up the highly elaborated nitrogenous material in the leaves, stems and roots. As the amino nitrogen increases at a much greater rate than the total nitrogen, there

must necessarily be a marked breaking down and decomposition of the proteins present in the original seed. This fact is also further emphasized in that there is a decided increase of amino nitrogen when expressed as the percentage of total nitrogen.

From the figures given in the foregoing table, it is seen that when the percentage of the total nitrogen decreases as indicated by the results obtained from the seedlings in their natural condition, the percentage of amino nitrogen increases. When this data is expressed in terms of dry material there is a slight increase in the total nitrogen and a very decided increase in the amino nitrogen.

In the case of the seven-day seedlings, the plumules, cotyledons and roots were analyzed separately and the following results were obtained:

TABLE II.

	Natural.		Dry material.		Amino nitro., Total nitro. Per cent.
	Total nitrogen. Per cent.	Amino nitrogen. Per cent.	Total nitrogen. Per cent.	Amino nitrogen. Per cent.	
Plumule.....	0.832	0.301	7.021	2.540	36.18
Cotyledon.....	1.534	0.202	3.36	0.421	12.53
Root.....	5.33	1.705	31.99

From the above it is seen that the plumule contains a much greater amount of amino nitrogen, which undoubtedly serves as a food supply for the newly forming leaves and stems. It was expected that the cotyledon would show a greater percentage of amino nitrogen, owing to the decomposition of the protein material that it contained. However, this was not the case, and it is probable that any amino acids that are formed there are translocated to the roots and the stems. This is further indicated by the fact that the percentages of the amino nitrogen in the plumule and the root are much greater than in the cotyledon.

The leaves, the stems near the top, and those near the roots of the plant, were subjected to analysis in the fourteen-, twenty-one and thirty-eight-day plant with the following results:

TABLE III.

	Natural.		Dry material.		Amino nitro., Total nitro. Per cent.
	Total nitrogen. Per cent.	Amino nitrogen. Per cent.	Total nitrogen. Per cent.	Amino nitrogen. Per cent.	
14-Day leaves.....	1.52	0.297	9.43	1.830	19.41
21-Day leaves.....	1.52	0.244	9.29	1.495	16.09
38-Day leaves.....	1.46	0.209	8.35	1.195	14.32
14-Day stem (top).....	0.745	0.303	7.801	3.173	40.67
21-Day stem (top).....	...	0.283	...	2.973	...
38-Day stem (top).....	0.807	0.226	8.54	2.390	27.99
14-Day stem (root).....	0.693	0.300	8.59	3.717	43.30
21-Day stem (root).....	0.688	0.275	8.75	3.500	40.00
38-Day stem (root).....	0.675	0.187	8.54	2.364	27.68

The total nitrogen remains fairly constant in the natural leaves, but there is a noticeable decrease in the amino nitrogen. When these results are expressed in terms of the dry material, it is seen that there is a decrease in both the total and amino nitrogen as the plant increases in age. The same may be said of the stems both near the top and the bottom of the plant. It is also noticed that the amino nitrogen in the stems near the lower part of the plant are just a little less in percentage than the sample taken near the leaves.

In the case of these older plants it was impossible to get good, reliable results from the analysis of the roots because of the great difficulty of cleaning and freeing them from foreign materials. The results that were actually obtained from the analysis of the roots seemed to indicate a smaller percentage of amino nitrogen than was obtained in the stems. It also seems probable that the extreme ends of the roots contained a much smaller amount of amino nitrogen than the upper of the root.

CLARK COLLEGE, WORCESTER, MASS.

NEW BOOKS.

Landolt-Börnstein Physikalisch-Chemische Tabellen. Fourth edition, revised and enlarged. Prepared under the direction of DR. RICHARD BÖRNSTEIN AND DR. WALTHER A. ROTH. Berlin: Julius Springer. 1912. pp. xvi + 1310. Price, M. 59.

The greatest shortcoming of the previous editions of this indispensable work has been the entire lack of tables of certain important and much used data. The removal of this deficiency is responsible for the greater part of the increase in size of this edition over the previous one. Among the new tables the following may be mentioned: Homogeneous Gas Equilibria, Equilibria between Organic Substances, Distribution Coefficients, Ionization Constants, Conductivity Data for Non-aqueous Solutions, Hydrolysis Data, Radioactive Constants, and an extended table giving the chief physical properties of all of the more important organic compounds.

E. W. WASHBURN.

Notes on Elementary Inorganic Chemistry. By F. H. JEFFERY. Cambridge University Press. G. P. Putnam's Sons: New York. i + 55 pp. Price, 60 cents.

The purpose of the author of this small volume has been to present "short summaries of certain facts and reactions which are commonly included in a course on elementary inorganic chemistry." It is intended that the book be used in connection with lecture and laboratory work in order that the notes presented may "serve for revision purposes" and also that they may "afford the comparative beginner groups of facts which he might find difficult to coördinate for himself." Among the ten chapter headings are found such topics as: Acids, Bases and Salts, Oxidation and Reduction, The Action of Certain Acids on Some Metals, and Certain

Examples of Electrolysis. The author has brought together in small compass many of the facts in reference to the elements and compounds which are usually discussed in the beginning courses in our colleges and

the beginner in the science would have been greatly aided in the coördination of the facts of chemistry and some little use has been made of such useful instruments as the Periodic Law and also of some of the more commonly accepted theories. The almost entire absence of the terminology of these theories save in the chapter on "Certain Examples of Electrolysis" would seem to be unfortunate for the student. Some of the notions in reference to chemical equilibrium could have been introduced with great benefit in the chapter on "The Preparation of Certain Salts." Again, in the chapter on "The Action of Acids on Some Metals," a good opportunity is offered to present the electromotive series of metals as a useful aid in the work.

For the sake of clearness in the chapter on "Certain Examples of Electrolysis," it would have been better to represent the electrical charge carried by the cation and anion by different symbols rather than to use the same designation for both. Would not the student attach too great importance to potassium hydroxide by the first sentence on page 1; *viz.*, "The acids are compounds of hydrogen which react with potassium hydroxide in the following manner: if the acid be represented as HpA it reacts with p equivalents of potassium hydroxide KOH to form KpA and water only?" Owing to its brevity, many beginners would be satisfied with the sentence on page 2 that "Salts are compounds derived from acids," although the author discusses the idea of replaceable hydrogen in the next sentence.

However, this small digest of facts will undoubtedly serve a useful purpose. The chapters are composed of brief, numbered paragraphs with the topic to be discussed set in bold type. The book presents a pleasing appearance.

WM. LLOYD EVANS.

Manual of Quantitative Chemical Analysis. By J. O. FRANK AND E. A. CLEMANS. Oshkosh, Wis. Castle-Pierce Printing Co. 1914. 12 + 123 pp. Price, \$1.25.

This is a small, pocket-size book which, according to the preface, lays claim to being a laboratory manual only. This idea is consistently carried out, for the general descriptive matter is given in the merest outline. The deficiency is made up in a way by references to larger text-books; an excellent plan, if only there is a sufficiently large number of reference books at hand or a sufficiently small number of students to use them.

There are forty-nine laboratory exercises divided among gravimetric, electrolytic, volumetric and gas analysis. Twenty-two of these exercises call for the determination of some constituent of a pure salt, for example

copper in copper sulfate. The remainder of the list consists of methods for the preparation and standardization of volumetric solutions and for the analysis of commercial samples.

A systematic plan is used in presenting these laboratory exercises. There is first a short list of references to large text-books followed by a paragraph marked "Theory," in which a brief, general outline of the method is given. Next comes the "Method," the directions for carrying out the experimental work of the analysis in question. Finally there is a short list of questions followed by the chemical equations involved. This scheme of presentation and the concise directions for the laboratory work are the important features of the book.

The number and choice of the laboratory exercises to be used in the first year of quantitative work are a matter of opinion. Some prefer a large number of exercises containing many examples of pure salts, while others prefer a smaller number made up mostly of commercial samples, each exercise to be studied in detail. Those teachers who, like the authors, prefer a long list of determinations will do well to look into this little manual.

The book is, however, marred by the obvious failure to go through the proof sheets and eliminate such blunders as "dessicator" and such laboratory colloquialisms as "Using the result of your titration calculate the strength of your acid." The same carelessness is shown in not always looking up modern practice. On page 64 it is directed, in the emptying of a pipet, "to blow once or twice." To blow once is bad enough, but to leave the poor student the choice of blowing once or twice—! The above are typical of a large number of cases that detract from an otherwise good laboratory manual. Perhaps, though, the reviewer feels too strongly that there should be a direct relation between the accuracy of scientific work and the accuracy of writing about it. C. W. FOULK.

Principles of Quantitative Analysis. An Introductory Course. By WALTER C. BLASDALE, Associate Professor of Chemistry in the University of California. D. Van Nostrand Company, New York. 1914. x + 394 pp.; 70 ills. Price, \$2.50 net.

In this work the author presents the fundamental principles of quantitative analysis, and outlines a method by which a working knowledge of the subject can be attained. This is done by a scheme of classification, which is based upon the different types of chemical and physical equilibria.

The subject matter is arranged in ten sections as follows: 1. General features of gravimetric processes, 77 pp. 2. Gravimetric gas-evolution processes, 33 pp. 3. Gravimetric precipitation processes, 84 pp. 4. Gravimetric solution and extraction processes, 21 pp. 5. Partition processes, 14 pp. 6. General features of volumetric processes, 22 pp. 7.

Volumetric processes involving precipitation, 21 pp. 8. Volumetric processes involving neutralization, 33 pp. 9. Volumetric processes involving oxidation, 44 pp. 10. Physico-Chemical processes, 31 pp.

In the first section the author discusses many things of a general nature which pertain to quantitative chemistry, such as weighing, solutions, electrolytes, calculation of results, etc.

In presenting the quantitative procedures which follow the introduction, the theory of each process is discussed from the point of view of modern theoretical chemistry. Then some typical illustrations are given in considerable detail, with questions and problems appended which may be assigned to the students for solution.

The book contains the most important facts and theories of quantitative chemistry very well arranged and clearly stated. The most notable feature of the work is the special attention given to theory, much more of it having been introduced than is generally found in text books on quantitative analysis. The author states, "It is only through a definite knowledge of the theory of each step of the process that the analyst can work intelligently and effectively; the mechanical performance of such operations without understanding the reason for each step is not worthy of being dignified by the term 'quantitative analysis.'" This attitude toward the work is certainly the proper one, but it is feared that the author in his endeavor to emphasize this feature of the work has included some theoretical matter too advanced for the beginner in quantitative analysis. The subject matter, however, is so systematically arranged, with the greater part of the theory placed at the beginning of each section forming a separate part, that more or less of it can be considered, as desired.

The minerals, ores, alloys and products selected for analyses are substances which the chemist is likely to meet in ordinary practice and vary sufficiently to give the student a variety of principles and methods of procedure. The methods selected are standard ones and are clearly and accurately described with sufficient detail.

The questions and problems following the procedures have been well selected and emphasize the general principles made use of in the work.

References to original papers relating to many of the processes described are given.

The student who masters the contents of this book will certainly obtain a thorough foundation in quantitative analysis. C. F. SIDENER.

Monographs on Inorganic and Physical Chemistry. Intermetallic Compounds. By CARL H. DESCH, D.Sc., Ph.D., F.I.C. pp. vi + 116. Longmans, Green & Co., London, New York. Price, 90 cents.

Dr. Desch has accomplished a very useful piece of work in placing before the public in so concise and complete a form the data collected

in this field. To anyone who has not followed the recent literature on alloys, this small volume will be a surprise as to the extent of the work accomplished. The collection of data of this kind and the digestion of the literature is extremely helpful to those not making a specialty of the subject. The book is limited in its scope to the properties of and identification of compounds between metals, and assumes that the reader can interpret an equilibrium diagram.

The subjects discussed are: Thermal Analysis; The Principal Method for Identifying Intermetallic Compounds; Microscopic Structure; The Isolation of Intermetallic Compounds; Physical Properties; The Existence of Intermediate Compounds in the Liquid State; The Relations of Intermetallic Compounds to Carbides, Silicides, etc., and the Chemical Nature of such Compounds; Ternary Compounds.

The book is clearly written, well illustrated with diagrams, and a useful list of references is given.

HENRY FAY.

Outlines of Organic Chemistry. By F. J. MOORE, Professor of Organic Chemistry in the Massachusetts Institute of Technology. Second edition, rewritten. New York: John Wiley & Sons. 1914. xi + 325 pp. Price, \$1.50.

The present book, as suggested by the author, arose out of a course of lectures delivered almost exclusively to candidates for the bachelor's degree in Physics, Biology and Sanitary Engineering. An attempt has been made to present a "selection of topics which is somewhat different from that given to those who are fitting themselves to become organic chemists." The compounds discussed are selected because of their so-called practical importance or because of their convenient illustrative value in presenting fundamental principles.

Many topics of interest in organic chemistry, such as the synthesis of aceto-acetic ester, the Grignard reaction, etc., are omitted as not being of sufficiently vital interest to the classes of students concerned. In the case of simpler compounds, constitutional proof is presented in considerable detail. In other cases the author has avoided elaborate discussion and in some, the formulae alone are given.

Following the introduction there is given in Chapters 2-6, an elementary consideration of the saturated hydrocarbons, alcohols, acids, aldehydes, ketones, amines and unsaturated hydrocarbons. More complex organic compounds are presented in Chapters 7-11, followed in Chapter 12 by a discussion of the chemistry of certain vital processes. In Chapters 13-18 aromatic hydrocarbons and their simple derivatives are presented and in the concluding chapter, a brief discussion of the theory of structure.

In considering his treatment of the subject one cannot but feel that the author might, with advantage, have drawn a little more fully upon illustrative material, particularly from the field of applied chemistry. This would have much enhanced the interest of the work without unduly lengthening

the book. Of advantage, furthermore, would have been the addition of lists of suggestive questions and problems at the close of the several chapters.

Dr. Moore has, however, produced a book which is well written and clear in the exposition of the subject matter. As a brief introduction to organic chemistry, it merits the attention not only of the class for whom it was designed, but also of those who intend to devote their attention more fully to pure chemistry.

H. C. BIDDLE.

A Study of Foods. By RUTH A. WARDALL AND EDNA N. WHITE. Boston, Mass.: Ginn & Company. 174 pp. Price, 70 cents.

This is an elementary treatment of foods and is primarily suited for teachers of food courses in secondary and extension schools. It should also be found useful in the home. The treatment of the subject matter is simple and non-technical; in fact no chemical formulation is found. There are 22 chapters with a brief description of the common food constituents given in the first chapter. The next 18 chapters are devoted to the natural food materials themselves and their uses in the dietary. The 3 additional chapters relate to food requirements, selection of foods and serving of meals. In many instances one wishes that the treatment might have been more extensive, for the authors write with clearness and accuracy of statement. Rarely is there to be found any of the fads and notions prevalent about foods.

On page 5 occurs the statement "heavy eating of meat may easily furnish more protein than is desirable and it is believed that meat protein may cause more harm than other proteins," for which we might ask for definite proof.

This work is more than a book of recipes, yet combines briefly the usefulness of the recipe book with descriptions of the properties and general composition of the foods themselves.

Appended to each chapter is a helpful list of references. The illustrations are good and the printing and book make-up all that could be desired.

**A STUDY OF THE SYSTEM: WATER, POTASSIUM IODIDE AND
IODINE AT ZERO DEGREES.**

BY GRINNELL JONES AND MINER LOUIS HARTMANN.

Received November 30, 1914.

This investigation was undertaken as a necessary preliminary step in the study of the temperature coefficient of the free energy of formation of silver iodide from its elements. The method of procedure in determining this free energy was to measure the electromotive force of cells in which silver iodide is reversibly formed from silver and iodine at 0° and 25° . One-half of these cells consisted of a silver electrode surrounded with solid silver iodide immersed in a dilute potassium iodide solution; the other half consisted of a platinum electrode surrounded by solid iodine immersed in a saturated solution of iodine in dilute potassium iodide solution.

In order to apply a correction for the potential at the boundary of the two solutions and a correction for osmotic work involved in the operation of the cell, it is necessary to know the concentration and mobility of the potassium, iodide and tri-iodide ions present in each half of their cell at two different temperatures.

The necessary information in regard to the ionic mobilities and concentrations at 25° is furnished by the investigation of Bray and MacKay.¹

¹ W. C. Bray and G. M. J. MacKay, *THIS JOURNAL*, **32**, 914 (1910); W. C. Bray, *Ibid.*, **32**, 932 (1910).

No other temperature is known to us.¹ It was, therefore, decided to make a series of dilute potassium iodide solutions saturated with iodine at 0°. This study necessarily follows closely the methods used by Bray and MacKay, both in experimental procedure and in the interpretation of the results. It is a pleasure to acknowledge our indebtedness to these authors for many valuable suggestions. We introduced a number of variations in the experimental methods, some of which were required because we were making our measurements at 0°, but with one exception these variations were probably without significant effect on the results. This exception is the determination of the change in viscosity caused by the solution of potassium iodide and of potassium iodide plus iodine in water. As will be shown more in detail in the following pages, a 0.1 *N* solution of potassium iodide has a viscosity only 0.982 of the viscosity of pure water at the same temperature. Therefore, the degree of dissociation of potassium iodide would be overestimated by about 1.8% by the usual method of calculation. After this solution is saturated with iodine at 0°, its viscosity is raised to 0.995 of that of water. Therefore, the change in conductivity when iodine is dissolved in potassium iodide solutions is not due wholly to the replacement of part of the iodide ion by the tri-iodide ion, but partly to a slower motion of all of the ions present. Bray and MacKay neglected this influence, but, fortunately, the error caused thereby at 25°, although greater than the other errors in the work of Bray and MacKay is much less than the errors which would have been caused at 0° by the neglect of this correction. Of course the influence of the change in viscosity is less with the weaker solutions.

Purification of Materials.

Water.—All of the water used in this investigation, either in the purification of chemicals or in making the solutions, was conductivity water obtained from the special still² in this laboratory. The distillation was made from alkaline permanganate solution, and only the middle portion was collected for use. It was collected hot in previously steamed bottles of "non-sol" glass. The specific conductance of this water prepared at different times varied from 0.24×10^{-6} to 0.7×10^{-6} at 0°.

Iodine.—Iodine was prepared by dissolving "C. P." resublimed iodine in a very concentrated potassium iodide solution, diluting and distilling off the iodine. It was then washed with water on a Büchner funnel to remove any salts which might have spattered over during distillation,

¹ H. M. Dawson, *J. Chem. Soc.*, **79**, 239 (1901), has studied the equilibrium $KI + I_2 \rightleftharpoons KI_3$ at 13.5°, but his purpose did not require the measurement of the electrical conductivity of his solutions.

² Our still was patterned after the one described by Noyes and Coolidge, *Proc. Am. Acad.*, **39**, 190 (1910).

and then reduced to hydriodic acid by adding yellow phosphorus. The reaction went very smoothly; after standing on the steam bath for a short time the solution was completely decolorized. The hydriodic acid was separated from acids containing phosphorus by distillation. The solution being more dilute than the constant boiling mixture, water came off first, and this fraction must have contained all the hydrocyanic acid, if any were formed during the process.¹ Acid boiling from 123° to 135° was collected.

The iodine was liberated from a portion of this acid by action of halogen-free potassium permanganate and sulfuric acid.² The precipitated iodine was thoroughly washed with water in a Büchner funnel and dried in a desiccator over sulfuric acid for nearly a year before use. A short time before use this iodine was resublimed in a current of dry air, the condenser consisting of a hard glass tube which fitted into the subliming apparatus by a ground glass joint.

Potassium iodide.—Another portion of the hydriodic acid, prepared as described above, was redistilled, reserving only the portion which distilled over between 125° and 127° for use in making potassium iodide. Kahlbaum's potassium bicarbonate, which contained some normal carbonate but no halogens, and which showed only a trace of sodium by the flame test, was recrystallized by dissolving in hot water, cooling and passing in pure carbon dioxide. This gave a mixture of carbonate and bicarbonate, which was dried centrifugally³ in platinum Gooch crucibles. It gave no flame test for sodium after this treatment. The hydriodic acid was added in slight excess and the solution concentrated by evaporation. The potassium iodide was then crystallized by cooling and the salt dried centrifugally. The salt had a slight yellow color due to free iodine. It was heated on an electric stove at 60° for twenty-four hours to drive off water, hydriodic acid and iodine. The salt thus prepared was perfectly white and when dissolved in water gave a solution which was neutral and contained no free iodine and no iodate. It was found to be unsafe to heat the salt above 60° because iodine is liberated and it becomes alkaline.

Experimental Methods.

The Preparation of the Standard Potassium Iodide Solutions.

The potassium iodide was dried to constant weight at 60° by reheating for several hours in the weighing bottle on an electric stove. It was then

¹ Commercial iodine sometimes contains traces of iodine cyanide which may be eliminated as described above. See G. P. Baxter, *Proc. Am. Acad. Arts and Science*, 40, 421 (1904).

² A little manganese peroxide was precipitated with the iodine owing to failure to secure the best proportions of the reagents. It was, however, completely separated later by subliming the iodine.

³ G. P. Baxter, *THIS JOURNAL*, 30, 287 (1908).

weighed and dissolved in a "non-sol" glass bottle in conductivity water to make a solution approximately 0.1 *N* and the exact weight of the solution was determined.¹

The mols of potassium iodide per thousand grams of solution is called the weight normality of the solution. The density of this solution at 0° was carefully determined in order that the mols per liter or volume normality could be calculated. The density determinations were made in a pycnometer of the familiar Ostwald-Sprengel type, which was modified by the addition of a small bulb in the larger capillary tube beyond the graduation mark, of sufficient capacity to prevent loss of liquid owing to expansion when the solution was warmed to room temperatures for weighing. It was provided with a ground glass cap over the capillary tip to prevent evaporation. It had a volume slightly greater than 26 cc. and its weight when filled to the mark was concordant on successive trials to within 0.5 mg., or about 2 parts in one hundred thousand. A similar pycnometer was used as a counterpoise when weighing.

All solutions weaker than 0.1 *N* were prepared by dilution of a stronger solution by weight rather than by volume. Conductivity water was added to a known weight of a standard solution in a "non sol" bottle and the weight of the more dilute solution determined. The volume normality of the diluted solution at 0° was calculated with the help of the density. This procedure is more accurate than dilution by means of pipets, since the results are not influenced by uncertainties in drainage or temperature. These advantages are especially marked if it is necessary to know the concentration of solutions at temperatures far removed from room temperatures.

Conductance Measurements.

The conductance measurements were made by means of a slide-wire bridge of the roller type made by Leeds & Northrup. The bridge wire was manganin about two meters long with scale divisions of approximately three millimeters. The bridge wire was calibrated against the resistances of two Leeds & Northrup decade boxes, which had been standardized by the Bureau of Standards. The resistances used were made of manganin wire wound according to the Chaperon² principle to reduce self-induction and static capacity. These resistances were checked against standard resistance boxes and were found to be free from significant errors. A small condenser was used, when necessary, to balance the capacities of the resistance box and the conductivity cell, as recommended by Kohlrausch and Holborn.

A commutating device on the bridge allowed the ends of the wire to be reversed or commutated, and this was done in every case, although

¹ All weights have been corrected to vacuum.

² Chaperon, *Compt. rend.*, 108, 799 (1889); Kohlrausch and Holborn, p. 58.

no variation in resistance was found by reversing the position of the resistance box and the conductance cell. Readings on the bridge were reproducible to one part in five thousand. The conductance cells were of the pipet type.¹ The cell constants were determined exactly according to the directions of Kohlrausch and Holborn, "Leitvermögen der Electrolyte." The constant of No. 1 was found by E. K. Strachan to be 4.077 at 0°, using both 1 *N* and 0.1 *N* potassium chloride. We determined the constant of No. 2 using 0.1 *N* potassium chloride and found it to be 0.6222, which agrees exactly with the result of Washburn and MacInnes on the same cell obtained a year before. The constant of cell No. 3 was determined to be 0.06198 by comparison with No. 2 by using the same dilute solution in both cells. This result agreed exactly with that obtained by C. G. Derick, using 0.01 *N* potassium chloride. The conductance of the water used was determined by means of a cell with platinum-iridium electrodes about 3 cm. in diameter and 1 mm. apart. The surfaces of these electrodes were sand-blasted, but not covered with platinum black. The constant of this cell was 0.0294.

The conductance cells were kept during measurement in large Dewar tubes filled with distilled water and finely cracked ice made from distilled water.

An approximate setting having been made on the bridge, sufficient time was allowed to insure that the cell was at 0°, and then the final adjustment was made. This precaution was necessary because the solutions, especially the concentrated ones, became heated by the current from the induction coil, thereby decreasing the resistance. In all cases the ends of the bridge were commutated and readings made with the resistance in the box both higher and lower than the resistance of the solution in the other arm of the bridge. These values agreed within 0.1%.

The specific conductance of the water used in making the solutions was always measured and subtracted from the observed conductance of the solutions. This was never larger than 0.7×10^{-6} at 0°.

Saturation of the Potassium Iodide Solutions with Iodine.

The saturation of the potassium iodide solution with iodine was accomplished by shaking the solution with an excess of iodine in 250 cc. "non sol" glass-stoppered bottles in a shaking machine working in a bath of finely cracked ice and distilled water. The shaking was accomplished by means of a simple reciprocating motion from a crank on a fly wheel, and driven at high speed by a motor. The piston rod was supported

¹ See E. W. Washburn and D. A. MacInnes, *THIS JOURNAL*, 33, 1688-9 (1911) for a diagram and description of the type of cell used. These authors point out that this type of cell has important advantages over the usual form. Our cell No. 2 was the same as Washburn and MacInnes' cell No. 2. Our Nos. 1 and 3 were similar to theirs, but not the identical cells.

at an angle in order to secure the greatest efficiency in stirring in the bottle. The machine made about 200 strokes per minute. After the bottle was filled almost full of the solution under investigation, and an excess of solid iodine had been added, the stopper was inserted and a rubber "cap" was then slipped over the stopper and neck of the bottle and wired on to prevent the water of the ice bath from reaching the ground glass joint. The bottle was shaken in the ice bath for one and a half hours or more. Experiments were made which showed that this amount of shaking gave complete saturation.

After saturating with iodine, the electrical conductivity, density and free iodine dissolved were determined. The bottle was first allowed to stand for a short time to allow the iodine to settle and then the conductance cell was filled directly from the bottle without filtering, since the presence of particles of solid iodine could do no harm. A portion for the density determination was forced by air pressure through a tube containing a small bulb filled with tightly packed asbestos, which served as a filter, into a beaker cooled with ice and from this at once transferred to the pycnometer.¹ Several portions of the solution for analysis were forced in the same manner into weighed glass-stoppered flasks. The filtering bulb was below the liquid in the shaking bottle, and so it was always at 0°, thus preventing any warming of the solution while in contact with solid iodine. The flasks containing these samples were allowed to warm up to room temperature, and were then weighed. They were then cooled again with ice to condense the iodine vapors before the flasks were opened for titration, in order to avoid loss of iodine. In the later experiments several grams of solid potassium iodide were added to the flask and weighed with it before the sample was forced into the flask. This reduced the vapor pressure of iodine and thus served to prevent loss.

The free iodine was titrated by means of standard solutions of sodium arsenite containing a large amount of monosodium and disodium phosphates in the proportions recommended by Washburn,² who has clearly demonstrated that this is a very accurate titration when carried out under the proper conditions. Two solutions about 0.15 *N* and 0.007 *N*, respectively, were used. These titrations were carried out entirely by means of weight burets for the sake of accuracy, the final approach to the end point being accomplished with the dilute solution. In rare cases the end point was passed accidentally and in these cases a dilute iodine solution, approximately 0.006 *N*, was used. This solution was standardized against the dilute arsenite solution. These arsenite solutions were standardized against known weights of pure dry iodine, the weighing

¹ The first 5 or 10 cc. which came through were always rejected.

² E. W. Washburn, *THIS JOURNAL*, 30, 31 (1908); Washburn and Bates, *Ibid.*, 34, 1355 (1912).

bottle being opened under the arsenite solution to prevent loss of iodine. These standardizations were concordant within 0.02%, which was ample for the present purpose.

We found that a very satisfactory method of determining when the iodine was all reduced was to titrate until the very faintest yellow color remained. Then about 5 cc. of pure benzene were added and the solution shaken violently. The small trace of iodine dissolved in the benzene gave a pink color, which could be easily seen. Dilute arsenite solution was then added drop by drop until the pink color in the benzene layer had disappeared after shaking.

Viscosity Measurements.

The viscosity measurements were very kindly made for us by G. Y. Williams.¹ The viscosities of potassium iodide solutions approximately 0.1 *N* and 0.05 *N* were measured at 0° (see Table III, Column 5, for the results) and at 25° (Table IV, Column 5) and then these solutions were saturated with iodine at 0° and the viscosity determined again at 0° (Table III, Column 9) and at 25°. Since these solutions were not quite saturated at 25°, a slight correction has been made on the assumption that the small additional amount of iodine had the same proportional effect on the viscosity. The results are given in Table IV, Column 9. It is believed that these viscosity data are accurate within 0.1%.

The Experimental Data.

The experimental data for the solubility, density and conductance are shown in Tables I and II. The figures for the conductance are the averages obtained by commutating the bridge-wire and changing the resistance used. The figures for the solubility of iodine are the averages obtained by titrating two or three portions of the same solution. When more than one set of data is given for the solutions, saturated with iodine, they represent separate saturations with iodine of the corresponding potassium iodide solutions. Except in a very few cases, the conductance data are concordant within 0.1%. The solubility data do not agree so well, discrepancies of 0.2% being common. In a few cases discrepancies up to 1%, and in one case up to 4%, were encountered, but a repetition of the experiment and a plot of the results at different concentrations enables us to reject the erroneous results. These occasional erratic results were probably due to small particles of solid iodine passing the filters. Bray and MacKay¹ also found it impossible to secure as great conductance in the solubility data as in the conductance data.

The last column gives the volume normality of the solutions saturated with iodine corrected for the change in volume, which occurs when iodine is dissolved.

The solubility of iodine in mols I_2 per liter in potassium iodide solutions at 0° is expressed within the limit of error of our experiments up to and including 0.05 *N* by the linear equation, $(I_2) = 0.000638 + 0.472 c$, *c* being the concentration of the potassium iodide solution. A 0.1 *N*

¹ Bray and MacKay, *THIS JOURNAL*, 32, 919 (1910).

solution dissolves about 1% more iodine than the result given by this equation.

The density determinations were carried out with the three strongest solutions only, because the density was found to be a linear function of the concentration with an accuracy much surpassing our needs. For potassium iodide solutions

$$d_{40}^{0^{\circ}} = 0.99987 + 0.1246 c.$$

For the same solutions saturated with iodine,

$$d_{40}^{0^{\circ}} = 0.99987 + 0.2205 c.$$

The Equivalent Conductance of Potassium Iodide.

In order to simplify the interpretation and use of the experimental data, the results of the two series have been rounded off to even concentrations by volume, as shown in Table III. Experimental results which were known to be in error, and in a few cases data which for some unknown reason were obviously discordant with the other data, have been rejected in deriving this summary table. Column 3 gives the equivalent conductance of potassium iodide solutions at 0°. Similar measurements have been made by Sloan,¹ Kahlenberg,² and Harry C. Jones.³ These results have all been plotted ($\log C$ against Λ and by the Noyes method $1/\Lambda$ against $(C\Lambda)^{n-1}$) for comparison. Sloan's measurements extend from 0.04235 N to 5.1 N . In the small range where our measurements overlap with Sloan's, his values for Λ are about 0.2 higher than ours, and our results may be regarded as an extension of Sloan's curve into more dilute solutions. The curve ($\log C$ against Λ) representing Kahlenberg's results is very irregular, having two well-marked points of inflection in marked contrast to the curve representing our results, which has none.⁴ Three of Kahlenberg's points ($C = 1/32, 1/64, 1/128$) fall near our curve, but the others are about 1 to 1.15 units on the conductance lower than ours and Sloan's. The curve representing Harry C. Jones' results is lower than ours by 4 or 5 units of the equivalent conductance or about 6%. The measurements of Harry C. Jones on potassium iodide at 25° are lower than those of Bray and MacKay at 25° by about the same per cent.

The equivalent conductance of potassium iodide at infinite dilution has been found to be 83.5 by the plotting of $1/\Lambda$ against the corresponding value of $(C\Lambda)^{n-1}$, as proposed by A. A. Noyes.⁵ The value of n was found by trial plots using several values from $n = 1.3$ to $n = 1.6$, and choosing $n = 1.45$ as the exponent which gave the best straight line through

the points. This was also shown to be the best line by calculating the deviations by the method of least squares. The first series gave $\Lambda_0 = 83.47$ and the second series $\Lambda_0 = 83.49$. The rounded-off value 83.5 is accepted.

This method is purely empirical and every one who has used it has recognized that the results obtained with it are open to some doubt. Recently Bates¹ has argued that the values of Λ_0 obtained by this method are too high by about 0.5%. Still more recently Kraus and Bray² have proposed a general equation for the relationship between ionization and concentration of solutions, which they consider applicable to all solutions, both dilute and concentrated, aqueous and non-aqueous. This general equation is $c\gamma^2/1 - \gamma = K + D(c\gamma)^m$. Since $\gamma = \Lambda/\Lambda_0$ and the value of Λ_0 must also be selected to fit the data, this is a four constant equation.

An equation having a different form, but mathematically equivalent to the above equation, has been proposed independently by MacDougall.³

The argument of Kraus and Bray is based mainly on a discussion of data on non-aqueous solutions. They have applied their equation to a single aqueous solution, namely, potassium chloride, at 18°, using the data of Kohlrausch and Maltby. They reach the conclusion that the equivalent conductance of potassium chloride at infinite dilution at 18° is 128.3 instead of 130.1, which is the value given by Noyes' method and has been commonly accepted. Kraus and Bray's method thus gives a result which is nearly 1.5% lower than Noyes' method in this case. The method of Kraus and Bray requires a knowledge of the conductivity and viscosity of very concentrated solutions (up to several times normal). These data are not available in very many cases. They find it necessary to reject the data for solutions below 0.001 *N*, which by their method of plotting do not fall on the same curves as the data for all the stronger solutions.⁴ They conclude that these data are in error owing to the uncertainty in applying the water correction. Bates,⁵ on the other hand, lays especial

¹ S. J. Bates, *THIS JOURNAL*, **35**, 519 (1913).

² C. A. Kraus and W. C. Bray, *Ibid.*, **35**, 1315 (1913).

³ F. H. MacDougall, *Ibid.*, **34**, 855 (1912). MacDougall considers this a three constant equation, and assumes γ known, apparently overlooking the fact that Λ_0 must be selected to fit the data, and does not use the equation as a means of determining Λ_0 .

James Kendall, *Proc. Chem. Soc.*, **28**, 255 (1912), has proposed the equation $c\gamma^2/1 - \gamma = K + D(1 - \gamma/\gamma)$ which he derives theoretically from very improbable assumptions. He does not publish any attempts to test his equation by means of the available data. We have, however, convinced ourselves that it is not possible to find a value for Λ_0 which will make this equation agree with Kohlrausch's data on potassium chloride at 18°, and this equation therefore is not generally applicable.

⁴ Kraus and Bray, *Loc. cit.*, p. 1413.

⁵ Bates, *Ibid.*, p. 528.

emphasis on the data for these extremely dilute solutions. He says, "If these constants (equivalent conductances at infinite dilution) are to be known with a certainty greater than 0.1% it is necessary that accurate conductivity data be determined for solutions more dilute than 0.0001 *N*."

It is evident that a definite solution of this problem must await the collection and publication of much new data on the conductivity of both very dilute and very concentrated solutions and the viscosity of the latter. Pending the collection of the new data and the reinterpretation of the best of the old, and the general adoption of some new method of extrapolating to infinite dilution, it has seemed best to use the Noyes method in interpreting our data. Our results will then be consistent and comparable with the great body of figures in the literature dealing with ionic mobilities and ionization including the similar work of Bray and MacKay at 25°. The results calculated in this way will be equally useful for the calculation of the corrections to the electromotive force of our silver-silver iodide-iodine cells, because we do not need to know the absolute values of the concentration and mobilities of the ions in potassium iodide solutions and in potassium iodide solutions saturated with iodine, provided the ratios of these quantities are correct. We will, therefore, adopt provisionally the value 83.5 for the equivalent conductivity of potassium iodide at infinite dilution at 0°. Noyes and Falk¹ have calculated the identical value for this constant, using Déguisne's² data on the temperature coefficient of conductance. Déguisne's thesis does not give the actual conductance measurements but only the temperature coefficients. The most probable value of the equivalent conductance of the potassium ion appears to be 40.1. This is derived from the equivalent conductance³ of potassium chloride at infinite dilution at 0°, 81.4, and the transference number⁴ of the cation in this salt at 0°, 0.493. The equivalent conductance of the iodide ion at 0° is, therefore, $83.5 - 40.1 = 43.4$.

Referring again to Table III, Column 4 gives the degree of dissociation calculated by the usual formula $\gamma = \Lambda_c/\Lambda_0$. But since the viscosity of the more concentrated solutions is appreciably different from that of water, it will doubtless be more accurate to write $\gamma = \Lambda_c\eta/\Lambda_0\eta_0$, where η/η_0 is the relative viscosity of the solution to that of water at the same temperature, the results being given in Col. 5. Col. 6 gives $\Lambda_c\eta/\eta_0$, which is the conductivity to be expected in a solution of unit viscosity. This figure, from which viscosity effects have been eliminated, is a convenient figure to use in studying change in conductivity caused by adding iodine.

The Equivalent Conductance of Potassium Triiodide at 0°.

The experimental data concerning potassium iodide solutions saturated with iodine is also summarized in Table III, corrected to even concentrations, and a number of quantities calculated from the experimental data.

When iodine dissolves in potassium iodide, the volume of the solution increases and a correction must be applied, in the case of the stronger solutions, in order to compare them with the solutions of potassium iodide from which they were made. The change in concentration due to this volume increase was calculated for the stronger solutions, using our data for the density and concentration of these solutions. The concentrations expressed in terms of the total potassium salts ($KI + KI_3$) = ΣK in the solutions saturated with iodine are given in Col. 12.

Col. 13 gives the free iodine in the solution, that is, the total amount titrated with the arsenite solution. This includes free iodine dissolved in the water as I_2 and the iodine in the complexes ($I_3^- + KI_3$ and higher complexes if present).

The solubility of iodine in pure water was determined to be 0.000638 mols I_2 per liter (see page 256). Subtracting this amount from the total iodine gives $\Sigma I_3 = I_3^- + KI_3$ (assuming higher complexes absent).

Subtracting ΣI_3 from ΣK gives $\Sigma I = (I + KI)$ (Col. 15) the concentration of the iodide in the solution. In Col. 16, the ratio $\Sigma I_3/\Sigma K = r$ is given. This ratio is independent of the degree of dissociation, since it relates only to the total I_3 and total K .

The equivalent conductances of the solutions saturated with iodine are given in Col. 8. These equivalent conductances have been corrected for viscosity, and these corrected conductances are given in Col. 10.

The change in the equivalent conductance due to the solution of iodine to form the slower moving ion I_3^- is found by subtracting the data of Col. 10 from that of Col. 6. These differences are shown in Col. 11 ($\Delta\Lambda$).

If we assume that, when part of the potassium iodide is converted into potassium triiodide, there is no change in the degree of dissociation of the remaining potassium iodide,¹ then the ratio $\Delta\Lambda/r$ shown in the 17th column represents the decrease in equivalent conductance which would be

¹ This is in accord with what is known about the ionization of salts in mixtures.

"In a mixture of two salts with a common ion each salt has a degree of ionization equal to that which it has when present alone in a solution in which its ions have a concentration equivalent to that of the common ion in the mixture;" Arrhenius, *Z. physik. Chem.*, **2**, 285 (1888); Arrhenius, *Ibid.*, **31**, 218 (1899); MacGregor, McIntosh, Archibald and MacKay, *Trans. Nova Scotia Inst. Science*, **9** and **10** (1895-1899); A. A. Noyes, *Z. physik. Chem.*, **52**, 635 (1905); M. S. Sherrill, *THIS JOURNAL*, **32**, 741 (1910); G. M. J. MacKay, *Ibid.*, **33**, 308 (1911).

obtained if all of the iodide were changed into triiodide, and if the resulting triiodide had the same degree of dissociation that it has in the mixture. This does not involve the assumption that the degree of dissociation of potassium triiodide is identical with the degree of dissociation of potassium iodide. Subtracting this change of conductance from the equivalent conductance of potassium iodide solution gives the equivalent conductance of a solution of potassium triiodide of the concentration $= \Sigma K$, and having a degree of dissociation equal to the triiodide in the mixture. These data have been plotted in the same manner as the potassium iodide solutions, and the extrapolation made to infinite dilution. By this method the equivalent conductance of potassium triiodide at infinite dilution has been found to be 62.9. If the mobility of the potassium ion be taken as 40.1, that of the triiodide becomes 22.8.

The degree of dissociation of the triiodide is given in Column 19. On comparing this with the degree of dissociation of the potassium iodide corresponding, it will be noticed that the triiodide is slightly less dissociated below 0.02 *N* but in the 0.1 *N* and 0.05 *N* solution it is slightly more dissociated. The slightly smaller value for 0.001 *N* solution is probably not significant, since it is difficult to secure the same percentage accuracy in this dilute solution. Perhaps this exceptional behavior of the 0.1 *N* solution is only apparent and would disappear if the proper allowance could be made for the presence of higher complexes. The concentrations of the iodide and the triiodide ions and their ratio are given in the next three columns. This ratio is essentially constant for all the concentrations up to 0.05 *N* and 0.1 *N* and here falls off very slightly. This is somewhat remarkable in view of the previous work of Bray and MacKay at 25°. They found that at 25° the ratio I^-/I_3^- decreased from 1.14 to 0.99 with increasing concentrations from 0.001 to 0.1 *N* and became 0.35 at 1 *N*. No such marked deviation is found from the results of this investigation at 0°, although a slight tendency in that direction appears in the two stronger solutions. If this apparent deviation from the mass law at 25° is to be explained by the obvious assumption that a higher complex than KI_3 is formed, then the data at 0° would show that the formation of these higher complexes is much less at the lower temperature.

In the last column is shown the equilibrium constant for the reaction

obtained by multiplying the ratio of the preceding column by the solubility of iodine in water, 0.000638 mols per liter.

This equilibrium constant is slightly lower than that obtained by Fedotieff¹ in the study of the reaction,

¹ Fedotieff, *Z. anorg. Chem.*, **69**, 31 (1911).

He obtained the constant 735×10^{-6} .

The Solubility and Hydrolysis of Iodine in Water at 0° .

In order to determine to what extent the reaction

might interfere with the conductance measurements of the very dilute solutions, some pure water was saturated with iodine by shaking at 0° , and the conductance of the solution measured. The conductance of the water itself was measured after it had been shaken under the same conditions. The average of several determinations showed that the hydrolysis caused an increase of 0.6×10^{-6} mhos in the conductance. The solubility of the iodine was 0.0006383 mols per liter.¹

The reaction is further complicated by the side reaction

Combining the two equations, using the ratio $\Sigma\text{I}^-/\Sigma\text{I}_3^- = 1.125$ from Table III, gives

For every molecule of hydrogen ion produced, 1.471 mols of iodine are dissolved in forms other than I_2 . If the mobilities of the hydrogen, iodide, and triiodide ions are taken as 240, 43.4 and 22.8, respectively, then for the water solution assuming complete dissociation

$$\Lambda = 240 + 0.529 \times 43.4 + 0.471 \times 22.8 = 273.7$$

$$\text{and } c = \frac{\kappa \times 10^3}{\Lambda} = \frac{(0.6 \times 10^{-6}) \times 10^3}{273.7} = 2.2 \times 10^{-6} \text{ mols H}^+$$

produced. Since every mol of H^+ ion represents 1.471 mols of iodine, there are dissolved 3.2×10^{-6} mols of iodine in the form of HIO, I^- and I_3^- in the water. Subtracting this from the total solubility of iodine in water gives 0.0006380 mols I_2 dissolved.

The hydrolysis constant may now be calculated for reaction (1).

$$K = \frac{(\text{HIO})(\text{H}^+)(\text{I}^-)}{(\text{I}_2)} = \frac{(2.2)(2.2)(2.2 \times 0.53) \times 10^{-18}}{0.000638} = 9 \times 10^{-15}.$$

It is easy to show that hydrolysis is negligible in solutions containing 0.001 *N* KI. The iodide ion concentration in such a solution is 0.000514 and since $(\text{H}^+) = (\text{HIO})$ we have

$$9 \times 10^{-15} = \frac{(\text{H}^+)^2 \cdot 0.000514}{0.000638}$$

$$(\text{H}^+) = 1.05 \times 10^{-7}.$$

The increased conductivity is therefore

¹ This is lower than the value obtained by Fedotieff (*Z. anorg. Chem.*, **69**, 30 (1911)), who obtained 1.30 mg. atoms per liter = 0.00065 mols per liter.

$$\frac{1.05 \times 10^{-7} \times 273.7}{1000} = 0.029 \times 10^{-6}$$

which is less than the uncertainty in the water correction and entirely negligible. The increase in free iodine dissolved in the form of HIO and I_3 owing to hydrolysis is 1.05×10^{-7} mols HIO and $0.471 \times 1.05 \times 10^{-7}$ mols I_3 together equivalent to 1.6×10^{-7} mols I_2 , which is also negligible.

It is a well-known fact that chlorine water liberates free oxygen, especially in sunlight, and therefore the possibility of a similar reaction occurring with the much weaker oxidizing agent, iodine, was considered. On the other hand, strong potassium iodide solutions when exposed to air and sunlight liberate free iodine. We must, therefore, consider the possibility of the reaction $2I_2 + 2H_2O \rightleftharpoons 4H^+ + 4I^- + O_2$. There are no electromotive data which throw light on this question at 0°. A study of the available data on iodine and oxygen electrodes at 25° indicates that under the conditions existing in a water solution of iodine there is a very slight tendency (about 0.04 volts) for oxygen to be liberated. This, however, gives no indication of the velocity of the reaction.

Another conceivable reaction is $3I_2 + 3H_2O \rightleftharpoons 6H^+ + 5I^- + IO_3^-$. Since the conductance of water was only increased by 0.6×10^{-6} mhos by saturation with iodine, it is obvious that none of these reactions can occur sufficiently to cause an appreciable error in our results. We have assumed that the increased conductance is caused by the reaction $I_2 + H_2O \rightleftharpoons HIO + H^+ + I^-$, as seems most probable. It is evident that none of these reactions occurs to an extent great enough to influence appreciably either the conductivity of our solutions or the amount of iodine dissolved. Therefore, it did not seem necessary to carry out experiments to decide between these alternatives.

A Comparison of the Results at 0° with those of Bray and MacKay at 25°.

The influence of the viscosity on the results having been found to be considerable at 0°, it seemed to us important to determine how great this influence is at 25°, and, if necessary, correct the results of Bray and MacKay.

The viscosities of a 0.1 *N* and 0.05 *N* solution of potassium iodide and the same solutions after saturating with iodine were found at 25° with the help of G. Y. Williams, the results being shown in Cols. 5 and 9 of Table IV.

The viscosities of the weaker solutions were obtained by interpolation. These results have been used to correct the results of Bray and MacKay, the results being shown in Table IV. The weaker solutions are, of course, not influenced by this correction, but it seemed worth while to reprint the figures in order to facilitate a comparison of the results at 0° and at

25°. Col. 7 shows that the degree of dissociation of potassium iodide is greater at 0° than at 25°. Bray and MacKay found the same effect of temperature on comparing their results at 25° with those of Kohlrausch at 18°. The influence of temperature on the dissociation of KI₃, on the other hand, although slight, is in the opposite direction. The solubility of iodine in potassium iodide solutions is somewhat less at 0° than at 25° (Cols. 13 and 14).

The most interesting comparison is found in Cols. 16, 22 and 23, which show a much greater constancy at 0° than at 25°. It is evident that the results conform to the requirements of the mass law much better at 0° than at 25°.

There is a slight deviation in the results at 0° with the two strongest solutions in the same direction as at 25°, but the deviations are comparatively small. The deviation from the mass law at 25° is discussed in considerable detail by Bray and MacKay, who reach the conclusion that the "activity of the ions is not proportional to their concentration."

Summary.

1. The conductances at 0° of potassium iodide solutions and of the same solutions saturated with iodine between 0.1 and 0.001 *N* have been measured.
2. The solubility of iodine in each of the solutions and in pure water has been determined.
3. The degree of dissociation of potassium iodide at 0° and 25° have been corrected for the change of viscosity of the solution.
4. The mobilities of the iodide and triiodide ions were found to be 43.4 and 22.8, respectively, at 0°.
5. The hydrolysis constant of iodine in water at 0° was found to be 9×10^{-15} .
6. The increase of the mass-law constant of the reaction $I_2 + I^- \rightleftharpoons I_3^-$ with the concentration of the solutions, which was found by Bray and MacKay at 25°, we now find at 0°.

HARVARD UNIVERSITY,
CAMBRIDGE, MASS.

ON THE ASSOCIATION OF MERCURIC CHLORIDE IN WATER SOLUTION.

By G. A. LINHART.

Received December 7, 1914.

It is a generally accepted fact that mercuric chloride in solution of a pure indifferent solvent does not associate.¹ The data thus far published are the results obtained from a study of the molecular weight of mercuric chloride in several organic solvents,² and seem to justify the above con-

¹ Abegg's *Handbuch der Anorg. Chem.*, II, 2, 615.

² Castro, *Gazz. chim. ital.*, 28, II, 317; Salvadori, *Ibid.*, 26, I, 237.

clusion. The ebullioscopic data, however, relative to the molecular weight in water solution are wholly unsatisfactory, as no two sets of figures, not even of the same investigator, agree. Thus Beckmann¹ gives for the molecular weight of mercuric chloride 318 and 297, although the amounts of mercuric chloride used in each of these determinations differed only by about 2%. Again he gives 284 and 275 when the original amounts of mercuric chloride used differed only by about 0.4%. Finally he gives 342 as the molecular weight. The same is true of the work of Kahlenberg² and Landsberger³ on the same subject. Another striking example of this unusual behavior of mercuric chloride in water solution are the results obtained by Hantzsch and Vagt,⁴ and Morse⁵ from distribution ratio measurements of mercuric chloride between water and toluene.

In view of these obvious discrepancies and of others more involved⁶ the present work had been undertaken to discover, if possible, some general property of mercuric chloride in water solution, which would account for its peculiar behavior in the several cases cited above. It will be shown in this paper, both experimentally and theoretically, that the deviation in the molecular weight, as well as in the distribution ratio, is due to the presence in water solution of the double molecules of mercuric chloride to a considerable extent, and also that the degree of association varies with the concentration and temperature, and may be determined accurately by means of several physical-chemical methods.

From the work of Hantzsch and Vagt, as well as that of Morse, it is evident that the distribution ratio of mercuric chloride between water and toluene is not constant, but decreases with the dilution. As mercuric chloride exists in the form of simple molecules in organic non-aqueous indifferent solvents,⁴ this is exactly what would be expected, since only the simple molecules can then enter the toluene layer. It follows that the lower the concentration of the total mercuric chloride in the water phase, the lower will be the number of double molecules, Hg_2Cl_4 , and therefore the proportionately greater will be the number of simple molecules entering the toluene phase, thereby causing a gradual decrease in the distribution ratio of mercuric chloride between the water and toluene. That this is actually the case may be shown from a recalculation of the results of the authors mentioned above.⁷ A small correction, however,

⁷ See these in discussion of results.

had to be applied in order to make their results fit the theory developed in this paper, because these investigators analyzed the water phase only. This means that a 0.3% error (which is within experimental error in the use of the sulfide method) in the water phase would correspond to about 4% error in the toluene phase. In recalculating their results, therefore, the corrections were applied to the actual amounts of mercuric chloride found in the water phase (and these corrections were in all cases well within experimental error) and the difference between these and the total mercuric chloride was taken as the amount of mercuric chloride in the toluene phase. It might be stated here that the method developed in this work and described below makes it possible not only to remove every trace of mercuric chloride from the benzene or toluene but also aids greatly in the subsequent precipitation as mercuric sulfide by hydrogen sulfide.

In a recent investigation¹ of the complex salts that mercuric chloride forms with sodium chloride and barium chloride, respectively, it was found that in a saturated solution of either of the above salts a comparatively small amount of mercuric chloride does not exist as such, but is completely in the form of complexes, such as NaHgCl_3 , Na_2HgCl_4 , and BaHgCl_4 . Moreover, as these compounds have been found to be practically insoluble in benzene, the usefulness of this method of extracting the mercuric chloride from the benzene phase was at once apparent. Attention is also called to the fact that in order to establish the existence of the double molecules of mercuric chloride in water solution, the greatest possible degree of accuracy is required in carrying out the experiments, and the results obtained from the analyses of the benzene phase and not those of the water phase must be used in the calculation of the equilibrium constants of the simple and double molecules existing together in water solution. The amount of mercuric chloride in the water phase is found by difference.

Experimental Part.

Method of Procedure.—The desired amount of pure mercuric chloride was weighed out on a watch glass and washed into a calibrated 250 cc. flask by means of a funnel, sufficient water added to dissolve the mercuric chloride completely (which was hastened by frequent shaking) and the flask then placed in a thermostat. After the solution reached the temperature of the bath the flask was filled to the mark, was thoroughly shaken and then replaced in the thermostat. Of this solution 200 cc. were transferred by means of a calibrated pipet into a stout bottle of 500 cc. capacity provided with a ground glass stopper. 200 cc. of thiophene-free benzene, which was also at the temperature of the thermostat, were then added after which the glass stopper was carefully inserted and the bottle rendered airtight by pouring paraffin upon the depression be-

¹ The work on this subject will appear in a subsequent number of *THIS JOURNAL*.

tween the outer part of the stopper and the lip of the bottle. After the paraffin solidified and showed no air holes a piece of strong canvas strap, about two inches in width, was used in strapping the stopper to the neck of the bottle. (This precaution was found necessary, as the paraffin seal would sometimes soften and allow a perceptible amount of benzene to escape which could be noticed by its odor.) The bottles thus prepared were immersed up to the necks in a thermostat kept at constant tem-

perature. Every two hours for about ten hours the bottles were thoroughly shaken and then allowed to remain over night in the thermostat. Each bottle was then in turn carefully removed, placed up to the neck in a glass vessel containing water of approximately the same temperature as that of the thermostat. (This precaution both in the filling and in the subsequent withdrawing of the solution was taken because of the uneven expansion of the two phases, since 200 cc. of water at room tem-

perature would expand to about 201 cc. at 40° , while 200 cc. of benzene would expand to about 204 cc. under like conditions.) After removing the strap and the paraffin seal the groove was carefully wiped with a piece

Both of these curves (D and E) should coincide with C, which is the one theoretically calculated.

of filter paper, and the stopper gently tapped and removed without disturbing the two layers.

It has been found expedient in pipeting benzene not to apply suction,

but to blow the benzene into the pipet which was provided with a two-hole rubber stopper exactly fitting the glass bottle. Before inserting the pipet for the purpose of withdrawing the solution, the rubber stopper was so adjusted that the end of the pipet reached within about $\frac{1}{2}$ inch of the lower layer, in order not to disturb it. Of the 200 cc. of the benzene layer about three-fourths were slowly and uninterruptedly blown into the pipet to some distance above the 150 cc. mark, the upper end of the pipet stopped with the finger, the pipet slowly removed with the rubber stopper on it, and after allowing the benzene to flow down to the mark it was run into a 500 cc. separatory funnel. (The pipet was, of course, thoroughly rinsed with pure benzene after each operation, allowed to drain and then dried by means of a current of air.) 100 cc. of a clear saturated sodium chloride solution were then added, and the funnel vigorously shaken and finally allowed to remain at rest until the boundary line between the two layers became sharp. The lower layer was then run out into a 500 cc. beaker and the treatment of the benzene repeated with another 100 cc. of the clear saturated sodium chloride solution. Two treatments were found sufficient in most cases to remove every trace of the mercuric chloride from the benzene. To these 200 cc. of the saturated sodium chloride solution in the beaker containing the mercuric chloride were added 150 cc. of hot distilled water and a few cubic centimeters of pure hydrochloric acid. A slow current of well washed hydrogen sulfide gas was then passed into the solution (care being taken to keep the beaker always covered, thereby excluding possible oxidation of the hydrogen sulfide to free sulfur) until the precipitate was completely settled and the supernatant liquid became perfectly clear. This supernatant liquid was then passed through an ignited and weighed perforated platinum crucible fitted with an asbestos mat, the precipitate washed several times by decantation with freshly prepared warm hydrogen sulfide water, the precipitate washed into the crucible and the washing continued until all traces of chlorides were removed. It is important to note that the precipitate in the crucible cakes and shrinks, due to the suction, and that the crevices thus formed allow the wash water to be sucked through without effectively washing the precipitate. It is therefore necessary to plaster over these crevices with the flattened end of a glass rod. Also if the proper precautions have been taken in the precipitation of the mercuric sulfide, as well as in the preparation of the hydrogen sulfide water, the washing of the precipitate need not be followed by carbon disulfide and must not be followed by pure water, which would cause the mercuric sulfide to go through the asbestos filter in the form of colloidal mercuric sulfide. The precipitate was then dried in an oven between 105° and 110° to constant weight, allowed to cool in a desiccator and finally weighed.

A denotes the number of milligrams of mercuric chloride per 200 cc. of water solution.

Cw° denotes the number of millimols of mercuric chloride per liter of water solution.

³/₄B denotes the milligrams of mercuric sulfide actually obtained from the analyses of ³/₄ × 200 = 150 cm³. of the benzene phase.

Cb denotes the number of millimols of mercuric chloride per liter of the benzene phase.

Cw° — Cb = Cw, denotes the number of millimols of mercuric chloride per liter of the water phase.

$$\frac{Cw}{Cb} = R \text{ denotes the distribution ratio.}$$

$$C_{HgCl_2} = R_{\infty} Cb$$

$$C_{HgCl_2} = \frac{Cw - R_{\infty} Cb}{2}$$

$$(10)^4 K = \frac{C_{Hg_2Cl_4}}{C_{HgCl_2}^2}$$

Discussion of the Results.

From the form of the equation,

$$HgCl_2 + HgCl_2 \rightleftharpoons Hg_2HgCl_4 \text{ or}$$

$$K = \frac{C_{Hg_2Cl_4}}{C_{HgCl_2}^2} = \frac{1/2(Cw - CbR_{\infty})}{(CbR_{\infty})^2},$$

by means of which the equilibrium constants were calculated, it is evident that a knowledge of the true distribution ratio of the simple molecules, HgCl₂, between the water and the benzene (H₂O ← HgCl₂ → C₆H₆)

¹ See calculations at the end of the article regarding these figures.

is very essential. This value may be found either by working with dilutions (4 and 2 millimols per liter, respectively) at which practically all the mercuric chloride is in the form of HgCl_2 , when the resulting distribution ratios become concordant; or, by plotting the several ratios obtained from the experiments at more convenient concentrations, and extending the line connecting these points to the coördinate representing zero concentration. In the experiments at 25° the former, or experi-

Fig. 3.

Curve A is obtained from the theoretically calculated values and practically coincides with the curve representing Kahlenberg's figures.

Curve B represents the values observed by Beckmann. It will be noticed that the 5th, 7th and 10th points lie close enough to the calculated line. These are the only ones that yield constants which are concordant with those of Kahlenberg, or those theoretically calculated.

Curve C represents the figures of Landsberger.

mental, method was used, while in the experiments at 40° the graphical method was applied.

It will be noted also that the distribution ratio is slightly lower at 40° than at 25° . This is due to the fact that the rate of solubility of mercuric chloride is proportionately greater in benzene than in water up to a certain temperature, as is shown by the relative positions of the curves representing the solubility of mercuric chloride in water and benzene, respectively. This decrease in the distribution ratio with rise in temperature is observed

CURVES REPRESENTING THE ASSOCIATION OF MERCURIC CHLORIDE AND THE EQUILIBRIUM CONSTANTS BETWEEN 0° AND 100° .

Fig. 4.

also in the results of similar experiments with toluene by Hantzsch and Vagt.¹

Finally, attention is called to the fact that K remains fairly constant from extreme dilution to saturation, which fact leads to the plausible conclusion that Hg_2Cl_4 is the only complex formed in pure water solution, for the given range of temperature, and possibly for any temperature between 0° and 100° as will be shown further on.

Discussion of the Results of Hantzsch and Vagt, and of Morse.

It is evident from the experiments at 25° of Table I that the equilibrium constant K is equal approximately to 0.0003. Substituting this value of K and such value for R that would bring the necessary corrections within experimental error, in the equation

$$K = \frac{C_{\text{Hg}_2\text{Cl}_4}}{C_{\text{HgCl}_2}^2} = \frac{1/2(Cw^\circ - R_\infty Cl - Cl)}{(R_\infty Cl)^2}.$$

We have,

$$Cl = -\frac{R_\infty + 1}{4R_\infty^2 K} \pm \sqrt{\frac{Cw^\circ}{2KR_\infty^2} + \left(\frac{R_\infty + 1}{4R_\infty^2 K}\right)^2}.$$

The significance of the letters is the same as that of those in Table I, except that in place of *Cb* we have *Ct*. *Cw* may then be found by subtracting *Ct* from *Cw*^o. This procedure is legitimate, since these investigators analyzed the water phase only, although Morse claims to have analyzed the toluene phase also, by extracting the mercuric chloride from the toluene by means of water and subsequently evaporating the large volume of water solution of mercuric chloride, thus resulting to dryness. Realizing the unreliability of this method he has apparently not laid much stress upon the results thus obtained and has evidently made use of those found by the analysis of the water phase only, in the calculation of his results, which agree fairly well with those obtained by Hantzsch and Vagt.

¹ See discussion of results below under (b).

Further evidence of the existence of the double molecule of mercuric chloride in water solution is shown by the ebullioscopic measurements of Kahlenberg, Landsberger and Beckmann,¹ and by the cryoscopic measurements of Biltz.²

Discussion of the Results of Kahlenberg, Landsberger, Beckmann and Biltz.

The equilibrium constants were first calculated from the original data, and then by means of the average of these constants the calculated values were obtained from the following well-known relations:

$$(1) K = \frac{a}{g(1-a)^2} \text{ or } a = \frac{2Kg + 1}{2Kg} \pm \sqrt{-1 + \left(\frac{2Kg + 1}{2Kg}\right)^2}$$

$$(2) a = \frac{1-i}{1-n} \text{ or } i = 1 - a(1-n)$$

$$(3) i = \frac{271}{M} \text{ or } M = \frac{271}{i}$$

$$(4) D = \frac{520g}{100M} \text{ in the ebullioscopic measurements}$$

$$\text{and } \frac{1850g}{100M} \text{ in the cryoscopic measurements,}$$

where g denotes the number of grams of mercuric chloride per 100 g. of water; D , the rise in the boiling point or lowering of the freezing point, as the case may be; M , the apparent molecular weight; i , the ratio of the true and apparent molecular weights; n , instead of denoting a whole number as in the case of substances which dissociate, equals $1/2$, because two molecules associate to form one; $100a$, the percentage of the mercuric chloride associated in the water solution; and K , the equilibrium constant of the equation:

$$\text{or, } K = \frac{C_{\text{Hg}_2\text{HgCl}_4}}{C_{\text{HgCl}_2}^2} = \frac{ag}{(g-ag)^2} = \frac{a}{g(1-a)^2}$$

It is interesting to compare (a) the equilibrium constants obtained for the several temperatures 0° , 25° , 40° , and 100° , and (b) the percentage association in saturated solution of mercuric chloride in pure water at the given temperatures. For this purpose it is essential that the data from which the several constants were obtained be expressed in the same units; that is, the data must be expressed in millimols of mercuric chloride per liter, as in the distribution ratio measurements, or in grams of mercuric chloride to 100 g. of water, as in the ebullioscopic and cryoscopic experiments. The latter unit was chosen.

¹ *Loc. cit.*

² *Z. phys. Chem.*, 40, 199 (1902).

(a) From Table I we have at 25°, 286.6 millimols per liter corresponding to 7.9 g. of mercuric chloride per 100 g. of water; 18.35 millimols per liter of Hg_2Cl_4 corresponding to 1 g. of mercuric chloride per 100 g. of water. At 40° we have 346.0 millimols per liter of mercuric chloride corresponding to 9.62 g. of mercuric chloride per 100 g. of water, and 30.989 millimols per liter of Hg_2Cl_4 correspond to 1.7 g. of mercuric chloride per 100 g. of water.

Substituting these values in the equation:

$$K = \frac{ag}{(g - ag)^2}$$

and comparing the resulting constants with K for 100° and 0°, we have:

t	0°	25°	40°	100°
K	0.012	0.021	0.027	0.050

If these four values of K are plotted on millimeter paper against their respective temperatures, the line formed by connecting the points is practically a straight line.

(b) Since the equilibrium constant K for 100° is equal to 0.050 and since the number of grams of mercuric chloride dissolved by 100 g. of water at 100° is equal to 53.965, we can calculate the percentages of association from the relation

$$K = \frac{ag}{g(g - ag)^2}$$

or, $100a = 55.00\%$ of the mercuric chloride associated at 100°. In a similar manner the percentages of the association of the mercuric chloride in saturated water solution at 40°, 25°, and 0° were calculated and tabulated together with the equilibrium constants for the corresponding temperatures.

t	0°	25°	40°	100°
K	0.012	0.021	0.027	0.050
% association of mercuric chloride in saturated water solution.....	6.07	12.65	17.67	55.00

Summary and General Conclusions.

1. A method has been devised by means of which mercuric chloride may be removed from benzene quantitatively in a form very well adapted for the subsequent precipitation of the mercuric chloride by hydrogen sulfide.

2. By means of this method of analysis the proof of the existence of the double molecule of mercuric chloride in water solution was made possible by measuring the distribution ratio of mercuric chloride between water and benzene at 25° and at 40°, respectively.

3. The association of mercuric chloride in pure water is further established by the recalculated data of Morse, and Hantzsch and Vagt,

obtained from the measurements of the distribution ratio of mercuric chloride between water and toluene; of Biltz, obtained by cryoscopic measurements; and finally of Kahlenberg, Landsberger, and Beckmann, obtained by ebullioscopic measurements. Moreover, it is remarkable how closely the calculated values agree with those observed by the several investigators mentioned above. The differences between the calculated and the observed values are in every case well within experimental error, except in those of Beckmann; but even here the difference is lower than his own experimental error as is shown in the table.

4. From the fact that the equilibrium constants have been found to be fairly concordant from practically extreme dilution to saturation for a given temperature, it is reasonable to assume that Hg_2Cl_4 is the only complex in pure water at any temperature between 0° and 100° , and at any concentration.

5. It is interesting to note that the equilibrium constants from 0° to 100° all lie on practically a straight line, and also that the associated fraction of the mercuric chloride in the saturated water solutions between these temperatures, when plotted, lie on a perfectly smooth curve.

6. Finally it is hoped that by means of these equilibrium constants it may be possible to account for the many discrepancies and contradictory data given in the recent literature concerning the complex compound which mercuric salts form with other salts.

Method employed in this article of converting grams of mercuric chloride per 100 g. of water to millimols per liter of water solution and grams of mercuric chloride per 100 g. of benzene to millimols per liter of benzene solution and *vice versa*, by means of solubility and specific gravity data taken from the literature.

These figures were obtained from solubility data of mercuric chloride at 25° and 40° in water and benzene, respectively, by plotting on millimeter paper the number of grams of mercuric chloride per 100 g. of water against the temperatures, drawing a smooth curve along the points and reading off the figures (which are enclosed in parentheses in table) for any desired temperature accurately to three significant figures. The figures thus obtained were converted to millimols per liter of solution by means of specific gravity data as follows:

FIND.

(a) The volume occupied by 1 g. of mercuric chloride, for example at 0°.

(b) Convert grams of mercuric chloride per 100 g. of water or benzene to millimols per liter of solution, at a given temperature.

(a)

From the table we have:

104.07 = the weight in grams of 100 cc. of solution, and (104.07), (0.0472) = 4.912 = weight in grams of HgCl₂ in 100 cc. of solution. 104.07 — 4.912 = 99.158 = weight in grams of water in 100 cc. of solution. $\frac{99.158}{0.99987} = 99.171$ = volume in cc. of water in 100 cc. of solution. 100.000 — 99.171 = 0.829 = volume in cc. of 4.912 g. of HgCl₂ in 100 cc. of solution. Hence, the volume occupied by 1 g. of mercuric chloride at 0° = $\frac{0.829}{4.912} = 0.169$ cc. In a similar manner were found the volumes occupied by 1 g. of mercuric chloride at 10°, 20°, and 30°, and the results tabulated below:

t.	Volume occupied by 1 g. HgCl ₂ .	Difference for 10°.	Average difference for 10°.
0°	0.169
		0.005	
10°	0.174	0.004	0.005
20°	0.178	0.007	
30°	0.185		

For the volume occupied by 1 g. of mercuric chloride at 25°, we may take the average of the volumes at 20° and at 30°, and the volume occupied by 1 g. of mercuric chloride at 40° we may find by adding the average difference 0.005 to the volume at 30°. Hence at 25° 1 g. of mercuric chloride occupies approximately 0.18 cc. and at 40° 0.19 cc.

Example: Conversion of solution at 40° of 9.62 g. of mercuric chloride per 100 g. of water to millimols per liter of solution:

$\frac{100}{0.99235} = 100.771$ cc. occupied by 100 g. of water

(9.62) (0.19) = 1.828 cc. occupied by 9.62 g. of mercuric chloride. Total volume occupied by 100 g. of water and 9.62 g. of mercuric chloride = 102.6 cc. Therefore,

102.6 : 1000 = 9.62 : x or, x = 93.7622 g. of mercuric chloride per liter of solution, and

$\frac{93.7622}{0.271}$ = 346.0 millimols per liter of solution of mercuric chloride and water at 40°.

THE ELECTRON CONCEPTION OF VALENCE. VI. INORGANIC COMPOUNDS.

By J. M. NELSON AND K. GEORGE FALK.

Received October 22, 1914.

In the previous papers of this series,¹ the view that two atoms when combining acquire opposite electric charges was developed and applied to various classes of compounds and reactions.

In this paper, the electron conception of valence will be applied more especially to compounds and reactions of inorganic chemistry. The natural method of studying the present problem is to take the classifications developed by Werner and to consider them from the point of view of the electron conception of valence. It is manifestly impossible in a paper such as this, to take up all the relations Werner has developed. Instead, only some of the more important will be chosen, and the application of the electronic view to these, considered.

In discussing the structures of inorganic compounds, it is useful to consider many of them as tautomeric. The conception of tautomerism has been most useful in organic chemistry, where a number of tautomeric forms of various substances have been isolated and their chemical and physical properties studied. Tautomeric formulas have also been proposed for certain inorganic substances. Recently, Bray and Branch,² as well as Lewis,³ developed valence views from this standpoint in papers entitled "Valence and Tautomerism."

The application of the electron conception of valence to the phenomenon of tautomerism was outlined in previous papers. It was shown that the algebraic sum of the charges on each atom in a substance capable of existing in tautomeric forms remains the same in each of the forms, although the arrangement of the atoms may be different. This may be illustrated by the formulas for hydrocyanic acid, nitrous acid, and ethyl acetoacetate:

¹ *School of Mines Quarterly*, 30, 179 (1909); *THIS JOURNAL*, 32, 1637 (1910); 33, 1140 (1911); 35, 1810 (1913); 36, 209 (1914); *Orig. Comm. 8th Intern. Congr. Appl. Chem.*, 6, 212 (1912); *J. prakt. Chem., (N. F.)*, 88, 97 (1913); *Proc. Amer. Philosoph. Soc.*, 53, 25 (1914).

² *THIS JOURNAL*, 35, 1440 (1913).

³ *Ibid.*, 35, 1449 (1913).

These formulas show that there is no oxidation or reduction reaction involved in the change of a tautomeric substance from one form to another. This is an important point in the further considerations.

Another fundamental relation is that which was described as onium compound formation and decomposition in a former paper,¹ and which involves the simultaneous loss and gain of a valence electron by one or more atoms of one or more molecules in a reaction. The formation of ammonium chloride from ammonia and hydrochloric acid according to

the equation² $\begin{array}{c} \equiv + \\ \text{NH}_3 \end{array} + \begin{array}{c} + - \\ \text{HCl} \end{array} = \begin{array}{c} \equiv \overline{+} \overline{+} - \\ \text{NH}_4\text{Cl} \end{array}$ in which the valence of the nitrogen is -3 in the one case and $-4 + 1 = -3$ in the other, is a simple example of this.

In beginning the study of inorganic compounds, it is advisable to consider a substance whose structure cannot be questioned. Platinic chloride must undoubtedly be represented by $\begin{array}{c} \overline{+} \overline{+} \\ \text{PtCl}_4 \end{array}$. To pass from platinic chloride to chloroplatinic acid involves no oxidation or reduction of any of the atoms involved as far as can be told, and the latter may, therefore, be represented by the formula

Chloroplatinic acid is a dibasic acid and may, therefore, also be written

¹ IV paper of this series, *THIS JOURNAL*, 35, 1810 (1913).

² This equation is probably not complete, as the presence of moisture is necessary for the reaction to proceed with finite velocity. It is possible, if the moisture acts purely catalytically, that this reaction would proceed as given although at a much smaller rate. In any event, the equation represents the change in the valence of the nitrogen atom to which it is desired to call attention in this connection.

platinum, or its state of oxidation, is $+6 - 2 = +4$ in chloroplatinic acid, just as it is in platonic chloride. The addition of hydrochloric acid to platonic chloride represents an onium compound formation. The negative chlorine combined with the positive platinum is not ionized, but the positive hydrogen combined with the positive platinum is ionized. The various chloroplatinic acids¹ may be considered next. In chloroplatinic acid, $\text{PtCl}_4 \cdot 2\text{HCl}$, HCl may be replaced by H_2O . This substance, pentachloroplatinic acid, $\text{PtCl}_4 \cdot \text{HCl} \cdot \text{H}_2\text{O}$, is also a dibasic acid. Without considering at present the possible mechanism of the reactions involved, but only the final formulas themselves, the structure of pentachloroplatinic acid must be analogous to that of chloroplatinic acid, or H_2O plays a part similar to that played by HCl . The formula for penta-

By analogy and in complete accord with the experimental facts, the positively charged hydrogens combined with the positive platinum are ionized, while the negatively charged atoms or groups combined with the positive platinum are not ionized. The other acids of this group given by Werner may be formulated in the same way:

¹ Werner, "Neuere Anschauungen auf dem Gebiete der anorganischen Chemie," III Edition (1913), pp. 40-1.

The fact that these acids are all dibasic proves that the acidity is **not** connected with the hydrogen of the hydroxyl groups,¹ and by comparing the whole series from chloroplatinic acid to platinic acid it is evident that the ionizable hydrogens are those combined directly with the positive central atom, platinum in this case. The salts of these acids may be formulated similarly.

Platinum evidently is not capable of taking up in onium combination an unlimited number of positively and negatively charged atoms or groups. The compounds just considered show that the maximum number of positive charges that a platinum atom is able to receive (or negative atoms or groups that it can hold in direct combination) is six.² However, in compounds in which this maximum positive valence is shown, the platinum has also two negative electrons or valences with which it holds two positive atoms or groups. While six is the maximum number of positive charges that the platinum atom can hold, it does not in such compounds attain a higher state of oxidation than that represented by four positive charges.

Possibilities of tautomerism exist for these platinum acids but there is at present no experimental evidence that they have been realized. A consideration of these possibilities might obscure and confuse the main points which the discussion of the structures just given, is intended to bring out, so that it will not be given in this connection. Such possibilities will be considered later in connection with other substances.

It will be of interest to take up next a number of acids containing oxygen. Sulfuric acid will be chosen as a typical example. Its structure is formu-

lated ordinarily as $\begin{array}{c} \text{O} \\ \parallel \\ \text{O} \end{array} \text{S} \begin{array}{c} \text{O} \\ \parallel \\ \text{O} \end{array}$ This structure is based upon a num-

ber of experimental facts, such as the reactions of organic derivatives of the acid and related compounds, the successive replacement of hydroxyl groups, etc. From the discussion of the platinum acids, it appears to be highly improbable for a substance with this formula to ionize as an acid. If, however, the structure is written in the tautomeric form, this difficulty disappears and sulfuric acid falls in line with the platinum acids. The tautomeric form of sulfuric acid is

The positively charged ionizable hydrogen is in direct combination with the positive sulfur, while the negative oxygen (or hydroxyl in the first

¹ Werner, *Loc. cit.*, p. 32.

² The maximum coordination number of Werner, *Loc. cit.*, p. 52.

form) combined with the positive sulfur is not ionized. The state of oxidation of the sulfur atom is the same (+6) in both cases. An equilibrium unquestionably exists between the tautomeric forms of sulfuric acid. An intermediate form in which only one hydrogen is in direct combination with sulfur is possible and undoubtedly exists. Its formula would be

tween the different tautomeric forms, together with the view that the hydrogen is ionized only when in direct combination with the central atom carrying a predominatingly positive charge, is suggestive in a number of directions. For instance, the anomalous behavior of strong electrolytes on ionization may, in part, be due to the existence of the tautomeric forms in solution and their different degrees of ionization.

It is evident that all oxygen acids and salts may be considered in the same way. The formulas for some follow:

The number of oxygen atoms in combination with the central atom depends upon the specific chemical nature of that atom. In general, Werner points out¹ that four or six oxygen atoms held by the central atom represent the two common types of compounds of this nature. Considered from the electronic point of view, the central atom in these two types in the ionizable forms would possess eight or twelve positive charges due to the combination with the negatively charged atoms or groups, while the ionizable positively charged atoms or groups would give the central atoms a certain number of negative charges or corpuscles. The difference between the number of positive and of negative charges of these central atoms represent their state of oxidation. In nitric acid, the state of oxidation of the nitrogen atom is represented by five positive charges; of chlorine in perchloric acid by seven positive charges; of phosphorus in phosphoric acid by five positive charges, etc. With phosphoric acid, other intermediate tautomeric forms are possible and probably exist as indicated with sulfuric acid. Here, as there, the experimentally measured ionization may depend to a great extent upon the equilibria between the

¹ *Loc. cit.*, p. 121.

tautomeric ionizable and un-ionizable forms. This is brought out also by the organic acids which must belong to this group. With acetic acid; for instance, the tautomeric forms would be represented by

The *a* form represents the ordinary chemical non-ionizable form of acetic acid. *b* represents the ionizable form in which the carbon atom of the carboxyl group has both gained and lost an additional corpuscle and the substance exists in the tautomeric form. As far as known, carbon does not form such onium compounds readily, although as pointed out in previous papers such modes of combination must exist from indirect evidence,¹ so that the small degree of ionization of acetic acid, and, therefore, of most organic acids, may be due mainly if not entirely, to the conditions of the equilibrium, the un-ionizable form predominating greatly. With regard to the salts of organic acids, and evidently of all acids, it would appear that the conditions of the equilibria are somewhat different and that there the concentrations of the ionizable forms predominate.

In the preceding discussion, it might appear at first sight as if the difference between the tautomeric forms as postulated is the same as that assumed by Bray and Branch and by Lewis in their view of compounds with polar and nonpolar valences. From one point of view, the differences and explanations advanced are similar. From a broader point of view, considering not alone one set of phenomena but the general relations of the substances, the assumption of the existence of polar valences at one time and nonpolar valences at another, leads to contradictions, some of which were pointed out in the fifth paper.²

It may be of interest to formulate some of the compounds given by Werner,³ according to the present basis:

¹ IV paper, p. 1817.

² THIS JOURNAL, 36, 209 (1914).

³ *Loc. cit.*, pp. 30-1.

This un-ionizable form is in equilibrium with the ionizable form whose structure was given earlier. In this equilibrium, the ionizable form appears to predominate, but it is conceivable that the un-ionizable form might predominate in related compounds. All of the chloroplatinic acids might be formulated similarly, but since this would be only repetition, it will not be done here.

Platinic chloride, PtCl_4 , combines with 2 NH_3 to form a neutral un-ionizable substance.¹ In strict analogy with the tetrachloroplatinic acid

just given, this substance must be formulated $\text{Cl}_4^{+6-2} \text{Pt} \begin{matrix} \text{N} \equiv \text{H}_3 \\ \text{N} \equiv \text{H}_3 \end{matrix}$.

The platinum is in the same state of oxidation as before, while the nitrogen is combined with the platinum in the onium manner. The existence of tautomeric forms does not appear to be common with compounds of this type where ammonia is combined with a metallic element.

A third ammonia molecule may be introduced into tetrachlorodiammine platinum. In this way, trichlorotriammine platinum chloride is obtained, and ionizes into a negative chloride ion and complex positive ion. Since chlorine in direct combination with platinum is not ionized, it must follow that the ionized chlorine is in combination with nitrogen. On this basis, the following formula may be proposed for this compound:

The state of oxidation of the platinum is unchanged. The negatively charged chlorine combined with positively charged platinum does not ionize, but when combined with negatively charged nitrogen it does ionize. This triammine salt is capable of taking up further molecules of ammonia. For each molecule of ammonia so added, a chlorine atom becomes ionizable, until finally with six ammonia molecules present in hexammine platinum chloride, all four chlorines may be present as ions. This last compound may be formulated

¹ Cf. Werner, *Loc. cit.*, p. 219, on the equivalence of water and ammonia as substituents.

In all of these compounds the valence of the platinum does not change but remains $+6 - 2$. The negative chloride ion is derived from the combination with negatively charged nitrogen in the onium form. Where chlorine is combined directly with positive platinum, it does not ionize. Where an ammonia molecule is combined directly with platinum with both valences forming onium linkings, no ionization appears. It is only when the nitrogen of the ammonia combines with one valence with the platinum and with the other with the chlorine to assume the onium form, that ionization of the chlorine takes place. It might perhaps be better to show in the formulas that the chloride ions in these complex platinum salts are derived from the ammonium part of the molecule and not from the platinum, but the symbolism introduced by Werner is so convenient that the formulas as given with all the charges indicated on the atoms may serve the purpose without creating confusion. The ionization of trichlorotriammine platinum chloride should follow the laws found experimentally for uni-univalent salts; of dichlorotetrammine platinum chloride, the laws for bi-univalent salts; and hexammine platinum chloride, the laws for tetra-univalent salts. The last two salts formulated above have a positively charged potassium atom in direct combination with positive platinum, and this potassium is ionized. These compounds have been discussed in sufficient detail before.

A summary of some of the relations just discussed may be of value here. The addition of ammonia to another molecule is due to its onium com-

$$\begin{array}{c} + - \quad + \equiv + - \\ \text{compound formation possibility. With } \text{HCl}, \text{H}_4 \text{N}^+ \text{Cl}^- \text{ is formed. With} \\ +6 = \quad = +7 - 1 \quad + \equiv + \\ \text{S O}_3, \text{doubtless } \text{O}_3 \text{S} \rightleftharpoons \text{N}^+ \text{H}_3 \text{ is first formed and then tautomerizes to the} \\ \text{better known } \text{O}_2 \text{S} \begin{array}{l} \nearrow \text{OH}^+ \\ \searrow \text{NH}_2^+ \end{array} . \text{ With } \text{PtCl}_4, \text{Cl}_4 \equiv \text{Pt} \begin{array}{l} \rightleftharpoons \text{N}^+ \text{H}_3 \\ \rightleftharpoons \text{N}^+ \text{H}_3 \end{array} \text{ is formed} \end{array}$$

and apparently does not tautomerize. Water plays an analogous part to ammonia,¹ and the relations may be formulated similarly. With

$$\begin{array}{c} + - \quad + \equiv + - \\ \text{HCl}, \text{H}_3 \text{O}^+ \text{Cl}^- \text{ is formed. ¹ Werner, *Loc. cit.*, pp. 257-64.

one set of phenomena predominates for one group in certain reactions and another set for another group in different reactions.¹

A brief comparison of the ammonia derivatives of platinous chloride, $PtCl_2$, with those of platonic chloride may be of interest. The series of platinous chloride ammonia compounds is as follows:²

In each of these compounds the platinum is in the same state of oxidation as in platinous chloride, +2. This differs in the state of oxidation from that of the platinum of $PtCl_4$, and it is only possible to pass from one series to the other by oxidizing or reducing the platinum.

The principles and relations developed for the complex platinum ammonia compounds may evidently be extended to any other compounds containing similar atoms or groups. Werner has given innumerable examples of these.

The relations of the complex ammonia salts are readily understood because the salt forming property of ammonia is so well known. If water were substituted for ammonia, similar classes and groups of compounds will be formed. The so-called basic properties of oxygen, or its ability to form onium compounds, are understood much better now than was the case relatively few years ago. If water were substituted for ammonia in $PtCl_4 \cdot 2NH_3$, the resulting compound $PtCl_4 \cdot 2H_2O$ tautomerizes and reacts as a dibasic acid as already explained. If water is substituted for ammonia in the platinum ammonia compounds containing more ammonia, then the water might act in the onium form just as the ammonia does. The negatively charged chlorine would then be combined with the oxygen of a water molecule, which is also combined with the platinum, and this negatively charged chlorine combined with negative oxygen would ionize. Whether such combination actually takes place with these compounds is questionable. It does, however, for such substances as hydrated

¹ It may be mentioned in this connection that the ordinary valence of the electronic point of view in which one corpuscle is transferred from one atom to another is analogous to the principal valence of Werner. The auxiliary valence of Werner corresponds in a number of compounds to the onium valence of the electronic treatment.

² Werner, *Loc. cit.*, p. 195.

nickel chloride, etc. The composition of the substance and the type of atoms in combination control the direction which is taken in these changes. These groups of substances include all those containing water of crystallization (or water of hydration in solution). If the water is held in onium combination, then the negatively charged element or group is combined directly with the negatively charged onium oxygen and is ionizable, while the positive ion will contain the atoms of the water molecule. Water or some similar substance must necessarily be present to bring about such ionization. This shows the importance of the solvent in ionization phenomena.

A brief discussion of the question of ionization may not be out of place here. From the considerations outlined in this paper, given in detail for a few typical substances but applicable in general, the following rule may be enunciated: *A positively charged atom ionizes only when in direct combination with an atom which contains a predominatingly positive charge; a negatively charged atom ionizes only when in direct combination with an*

atom which contains a predominatingly negative charge. In $\text{Cl}_4 \text{Pt H}_2$, negatively charged chlorine in direct combination with positive platinum does not ionize, but positively charged hydrogen in combination with platinum carrying $+6 - 2 = +4$ charges, ionizes. HCl in a solvent such as benzene does not ionize. In water, from the considerations ad-

vanced before (similar to those with ammonia), the compound $\text{H}_3 \text{O}^+ \text{Cl}^-$ is present.¹ The positively charged hydrogen combined with negative oxygen does not ionize, but negatively charged chlorine combined with oxygen carrying a predominatingly negative charge, ionizes. The ions here are $(\text{H}_3\text{O})^+$ and Cl^- .² With potassium hydroxide in water, the com-

compound formed would be

, and the ions $(\text{KH}_2\text{O})^+$

¹ A greater number of water molecules may be combined with the HCl, but the principle involved would be the same.

² The ionization of chloroplatinic acid and of hydrochloric acid indicates that hydrogen ions in aqueous solutions may be produced in two ways. With the former, the hydrogen ionizes directly, and after being separated, combines with and is in equilibrium with water and hydronium ions. With the latter, water combines first with the hydrogen chloride and then the hydronium ion is produced by ionization. In both cases, the final equilibrium between hydronium ion, hydrogen ion, and water, is the same; but the mechanism by which this equilibrium is attained is different in the two cases. The mechanism of the ionization of ammonium salts has not been taken up in this paper. However, it may be stated, that, since ammonia and water differ only in degree in onium compound formation properties, the explanation of the ionization of ammonium salts may be based upon reasoning similar to that given for the ionization of acids.

and (OH)⁻. The positively charged hydrogen and potassium combined with the negative oxygens are not ionized, while the negatively charged hydroxyl combined with the predominatingly negatively charged oxygen ionizes. These relations may be shown to hold generally. To go a step farther, and following Werner,¹ it may be stated that compounds of the first order do not ionize, but must go over into compounds of higher orders before ionization may appear.

An attempt is made in this paper to show the method by which the theoretical views of chemical structure based upon the classifications developed with the electron conception of valence may be used in connection with the classification based upon the relations founded on Werner's theory. It is manifestly impossible to enter into a systematic development in detail in a paper such as this. Instead, a few fundamental relations have been chosen and explained by means of typical compounds. A study of Werner's "*Neuere Anschauungen auf dem Gebiete der anorganischen Chemie*" on the basis of these relationships will show a large number of applications and extensions of these views to related compounds. It is believed that the views developed here and explained in connection with Werner's classifications add certain ideas to the latter, and especially bring out, perhaps in ways not evident before, a connection between the valence structures of inorganic and organic compounds. As a first exposition of these views it is to be expected that uncertainties and questionable points with regard to individual compounds and perhaps to some of the generalizations will appear, but on the whole, the further development of the views outlined appears to promise useful classifications of the compounds of inorganic chemistry as a branch of chemistry in general.

A SEARCH FOR AN ALKALI ELEMENT OF HIGHER ATOMIC WEIGHT THAN CESIUM.

BY GREGORY PAUL BAXTER.

Received December 10, 1914.

Two years ago the writer was fortunate enough to secure a considerable quantity of pollucite, which was obtained in the Paris, Maine, region. The material contained, approximately, 33% of cesium, rubidium and potassium oxides, chiefly cesium oxide, besides about 2% of lithium and sodium oxides. Through the assistance of Mr. C. C. Wallace the bases were extracted from the mineral by fine grinding and digesting with concentrated nitric acid. Treatment of the silicic acid residue with hydrofluoric acid showed that the extraction with nitric acid was very nearly complete.

¹ *Loc. cit.*, p. 89.

The nitric acid extract was evaporated until a very considerable proportion of the cesium nitrate separated as such. From the mother liquor the aluminum was precipitated with an excess of ammonia. The filtrate was then evaporated to dryness, and the residue was freed from ammonium nitrate by ignition. The cesium nitrate was then purified further from sodium nitrate by two crystallizations. The final yield was somewhat over 3.5 kg. of fairly pure cesium nitrate.

With so large a quantity of this rare substance, it seemed well worth while to examine it carefully for the presence of an unknown alkali element of higher atomic weight, although Richards and Archibald¹ have already made such a search, unsuccessfully, with a much smaller quantity of material. Therefore, the whole quantity was subjected to a prolonged fractional crystallization of the nitrate according to the usual plan, since it seemed likely from the solubilities of the nitrates of the alkalis that the nitrate of any alkali metal of higher atomic weight than cesium would be the least soluble of all. After 18 series of crystallizations the least soluble fraction, which contained about 3 g. of cesium nitrate, and the extreme mother liquor, were carefully examined. The mother liquor, besides containing a very large proportion of sodium with much lithium, contained also rubidium, potassium and thallium.² Some of these elements may owe their origin in this material to the presence of a small quantity of lepidolite in the pollucite. The quantities of potassium, rubidium and thallium were, however, so small that they could not be detected spectroscopically in the original mineral.

The flame spectrum of the extreme crystal fraction was compared visually with that of one of the large intermediate fractions and no line could be seen in the spectrum of one which was not present also in that of the other. The spark spectrum of these fractions in the visible and ultraviolet regions also was examined by photography with a Féry quartz spectrograph, by placing the chloride between platinum electrodes. Here again, the spectrum was identical with that of one of the intermediate fractions.

Furthermore, the radio-activity of the least soluble fraction was investigated by means of a sensitive, gold-leaf electroscope, and the rate of discharge of the electroscope was found not to be accelerated in the least by the crystals. The same result was obtained with the original pollucite and with the residues obtained from the extreme mother liquor.

Finally the atomic weight of the least soluble fraction was determined through the chloride by Mr. O. J. Stewart.³ The nitrate was changed

¹ *Proc. Am. Acad.*, 38, 449 (1903).

² Both H. L. Wells and T. W. Richards found thallium as an impurity in cesium material. *Proc. Am. Acad.*, 38, 449 (1903).

³ Mr. Stewart carried out this experiment at the close of two years' continuous experience in the exact analysis of chlorides.

to chloride by several evaporations with an excess of hydrochloric acid in a quartz dish. Then the chloride was twice crystallized from a cold solution by saturating with hydrochloric acid gas, with centrifugal drainage of the crystals in each case. As the purified product weighed less than a gram, only one analysis was made. The salt was fused in an atmosphere of dry hydrochloric acid gas in a platinum boat contained in a quartz tube. It was bottled in the Richards "bottling apparatus" and its weight, in vacuum, was found to be 0.72285 g. After solution in water it was precipitated with an equivalent amount of silver, 0.46336 g. (in vacuum) of the latter substance being found to be necessary. When an excess of silver nitrate was added and the precipitate collected and weighed, 0.61583 g. (fused, in vacuum) of silver chloride was obtained. From the amount of silver necessary, the atomic weight of the specimen is computed to be 132.84 ($\text{Ag} = 107.880$; $\text{Cl} = 35.457$), while the silver chloride corresponds to an atomic weight of 132.79. The average result is 132.82, a value essentially identical with the value chosen by the International Committee upon Atomic Weights, 132.81, which depends chiefly upon the work of Richards and Archibald.

It is certainly obvious that the foregoing experiments give no indication of the existence of an unknown alkali element.

The generous assistance of the Carnegie Institution of Washington has facilitated the progress of this work in many ways.

A METHOD OF DETERMINING THE HYDRATES FORMED BY A SALT.

By H. W. FOOTE.

Received November 30, 1914.

It is a well-known fact that the addition of sulfuric acid in sufficient quantity to the saturated solution of a hydrated salt with which the acid does not react, will cause the salt to crystallize, either as a lower hydrate or in the anhydrous condition. As an illustration, Taboury¹ has shown recently that beryllium sulfate yields the dihydrate when crystallized from a solution containing two volumes of concentrated sulfuric acid, although the tetrahydrate is the form crystallizing from water. This property of producing a lower hydrate is not peculiar to sulfuric acid alone, for the same effect may be produced by dissolving any other substance, provided it is sufficiently soluble and does not react chemically. Van't Hoff² has shown, for instance, that magnesium sulfate crystallizes with only four molecules of water instead of with seven, in the presence of a

¹ *Compt. rend.*, **159**, 180 (1914).

² *Sitzungsber. K. Akad. Wiss. (Berlin)*, **1899**, 340.

saturated solution of magnesium chloride, and the similar dehydrating action of alcohol is well known. Sulfuric acid, however, has one advantage over many substances in producing this result, for it is miscible with water in all proportions, making it possible to reduce the concentration of the water to any desired extent. On the other hand, this acid, at least when concentrated, will react with the majority of salts so that the method is limited chiefly to sulfates.

It is possible, in certain cases, to use this means of preparing lower hydrates to determine all the stable hydrates which a normal sulfate can form at a given temperature. It is evident from the phase rule that the three-component system composed of water, sulfuric acid and sulfate is divariant when the three phases vapor, solution and (solid) hydrate are present, since the phases equal the components in number. At a given temperature, therefore, the hydrate can exist in contact with solutions which vary in composition within certain limits. When two hydrates are present, the system becomes univariant. As a result, at a fixed temperature, there will be but one solution, of definite composition, in equilibrium with the two solid phases and vapor. The proportions of the two solids may, however, be changed so that the composition of the solid residue, as a whole, may be varied while the composition of the solution has a fixed value. It follows that in a series of solubility determinations of a salt, with continually increasing amounts of sulfuric acid, the presence of a pure salt is shown by varying solubility and constant composition of residue, while constant solubility and variable residue show that two salts are present as a mechanical mixture. In this way, it is possible to detect all the stable hydrates of a normal sulfate which form at a given temperature. An exception occurs when an acid sulfate forms before the anhydrous sulfate.

The solubility results are comparable with the vapor pressures of the hydrates alone, without sulfuric acid or solution. At a given temperature, a pure hydrate can exist in contact with pressures of water vapor which vary within certain limits, just as it can exist in contact with solutions of varying concentration. A mixture of two hydrates, on the other hand, has a definite vapor pressure just as it has a definite solubility. The measurement of vapor pressures in the two-component system is one of the standard methods for detecting hydrates and has been used repeatedly. The solubility method, where it can be used, has some advantages over the other, for solubility determinations in general are much simpler to carry out than determinations of vapor pressure, and they are also more accurate. It has an equal advantage with the vapor-pressure method, in showing the range of conditions under which a given hydrate can form.

A number of investigations have been published on the solubility of

sulfates in varying concentrations of sulfuric acid, in which the composition of the solid phases has been determined, but these have usually been for the purpose of determining the acid sulfates. In the case of sodium sulfate¹ and of lithium sulfate,² each salt forms but one stable hydrate, and these appear on the solubility curves. Kenrick³ has determined the equilibrium in the system ferrous sulfate, sulfuric acid and water, but an acid sulfate appears before the anhydrous salt is obtained, so that equilibrium between the latter and the monohydrate does not exist in this system. Similarly, an acid sulfate of zirconium is formed immediately following the tetrahydrate, and lower hydrates and the anhydrous salt cannot be obtained by means of sulfuric acid.⁴ So far as I am aware, no case has been investigated in which a number of hydrates and the anhydrous salt can all be obtained by means of sulfuric acid. Copper sulfate forms

⁵ These values were not determined directly and the calculated value for the pentahydrate is used.

three well-known hydrates and no acid salts interfere. It is, therefore, well suited to illustrate the relations mentioned.

A series of mixtures was prepared containing copper sulfate and water, with continually increasing proportions of sulfuric acid. The mixtures were heated, placed in glass-stoppered bottles sealed with paraffin, and rotated at 25° in a thermostat. No difficulty has been experienced, thus far, in reaching equilibrium after twenty-four hours. Samples for analysis were drawn off through a filter of glass wool. Copper was determined electrolytically and total sulfate by precipitating as barium sulfate. The proportions of copper sulfate and sulfuric acid could then be calculated. The residues were filtered on a filter plate covered with asbestos and washed with strong alcohol. Previous experience had shown that strong alcohol reacts very slowly with dehydrated salts which are insoluble in it. A small amount of acid, averaging less than 1%, always remained in the residue and causes an error in the water determination, giving somewhat high results. Chiefly for this reason, the analysis of the solutions is somewhat more accurate than that of the residues. The results obtained are given in Table I.

The results have been divided into groups in each of which either the solution or the residue remains constant in composition while the other varies. The percentage of copper sulfate falls off rapidly to rather low

values with increasing content of sulfuric acid so that the change in composition of solution is better illustrated by the results for sulfuric acid. In the figure, the results have been plotted. Ordinates represent percentage of water in the residue, and abscissas, the percentage of sulfuric acid in solution. This brings out clearly the range of conditions under which each hydrate forms, this being represented by the length of the horizontals. The conditions for the trihydrate are very narrow while the pentahydrate forms under the widest range, being stable in contact with solutions containing as much as 49% of sulfuric acid.

Solutions which are in equilibrium with two solid hydrates should have the same vapor pressure as that of the hydrates themselves.¹ The vapor pressure of the solutions in Nos. 7-9 of the table, for instance, should be equal to that of a mixture of the solid pentahydrate and trihydrate. Whether this way of determining the vapor pressures of hydrates will offer any advantage in accuracy or convenience has not yet been tested. Where the solubility of the salt is slight, as it is in the solution in equilibrium with anhydrous salt and monohydrate (Nos. 18-19), the vapor pressure of the solution is nearly that of the sulfuric acid solution alone.

I plan to extend this method to a number of sulfates which form more than one stable hydrate.

YALE UNIVERSITY, NEW HAVEN, CONN.

ELECTRIC SYNTHESIS OF COLLOIDS.

By JNANENDRANATH MUKHOPĀDHYĀYA.

Received December 11, 1914.

The present work was undertaken with a view to elucidate the process of formation of sols by the electric method first utilized by Bredig² for the preparation of sols in water, and subsequently modified by Svedberg³ for obtaining sols in non-aqueous media and of various substances besides metals. Bredig's own method is now a general one and has been extended by others to media other than water.

Much difference of opinion exists as to the process of formation of the sol by these methods. Wo. Ostwald, and others,⁴ hold that the process is of an electro-chemical nature and the substance goes into the liquid in the atomic form, under electric forces and afterwards becomes aggregated. Benedicks⁵ and others lay stress on the thermal side of the process and are of the opinion that the metal partly volatilizes and partly

¹ Foote and Scholes, *THIS JOURNAL*, **33**, 1309 (1911).

³ *Ber.*, **39**, 1703 (1906).

⁴ Cf. Ostwald's *Grundriss der Kolloid Chemie*.

⁵ *Z. Chem. Ind. Kolloide*, **11**, 263 (1912).

melts. Kutscheroff¹ has made experiments to prove his view of the process. He has studied the formation of sols using pairs of different metals as the two electrodes in Svedberg's method and has measured the amounts of the metals that pass into solution. He concludes that the metals go into the liquid as changed atoms, as shown by the fact that the ratio of the quantities of each passing into colloidal solution is the same as that of their equivalent weights. He, however, separates the coarse particles formed by the process by decantation and considers their formation to be due to a different process, possibly thermal, but adduces no reason for such assumption. His results show wide divergence from those of Svedberg. This divergence is due, possibly, to the uncertainty of the measurements, as we have to deal with small quantities of substances, and to Kutscheroff's arbitrary separation of the coarser particles.

Further, in cases of metals of variable valency, in calculating the ratio of the equivalent weights, in some cases he takes the metal to act with both valencies, sometimes with only one, thus acting quite arbitrarily, as pointed out by Benedicks. These considerations show that his data have not much significance.

Benedicks holds the view that the process of colloid formation is mainly of a thermal character and that the metal melts under the conditions into fine drops which remain suspended.

It seems possible that, under the intense heat of the powerful arcs produced in all these methods, the metal volatilizes and the surrounding liquid effects a sudden and rapid cooling and hence the vapor condenses to fine solid particles, resulting in a colloidal solution. Hence it was thought that if by any means the vapor of a substance which was solid at the ordinary temperature was produced in a liquid in which the substance was insoluble, a colloidal solution might be obtained.

To investigate the thermal effect it was decided to heat, under water, a substance which is insoluble in water. This was realized in the following way: The substance was finely powdered. A thin platinum wire was joined with two binding screws at the end of two stout copper wires clamped to two stands. These were in circuit with the adjustable resistance, two storage cells, an ammeter and a key. The platinum wire was thin enough to fuse with a current of 4 amps. in air. It was raised to a dull red heat by adjusting the resistance with a suitable current. The platinum wire was dipped in the pow-

Figure

¹ *Z. Chem. Ind. Kolloide*, 11, 165 (1912).

dered substance, which melted and stuck to the wire. In this way, with a little care, a thin, uniform coating of the substance was obtained on the wire.

The coated wire was then placed in a beaker containing "conductivity" water just covering the binding screws at a temperature of about 2°.

A current of 15 amperes was then sent through the wire. This could be done without fusing the wire, as the surrounding cold water carries the heat very rapidly by convection. Very soon the liquid becomes colored and a sol is formed. Thus with sulfur a milky white coloration, which becomes deeper as the current continues, is obtained in five minutes. Sols of selenium and arsenic have also been obtained in this method. Arsenic shows a very fine cone when a beam of sunlight is passed through it (Tyndall phenomenon), but its yield is very small.

Certain organic substances, such as α -naphthol, benzophenone, dibenzyl, anthracene, etc., were treated in the above way and a sol-like formation was observed in most cases. But most of these substances are slightly soluble at a high temperature, so that on cooling an opalescence due to the separation of fine particles is visible. Hence no definite conclusion can be drawn from these observations.

The temperature to which the wire is raised in this way is, after all, not so high, so it was decided to utilize the intense heat of the carbon arc.

An arc between two carbon electrodes was struck under water with 220 volts and a current of 2 amperes. The electrodes were placed vertically one above the other. The lower one was coated with the substance in the following way: The substance was melted in a crucible and the carbon rod with a flat head was dipped into it and hence a thick coating was obtained. The centre of the coating was scooped out with a knife, forming a small hole exposing the carbon. The upper carbon electrode was rubbed to a point and was held just above the coated one so that the pointed end of the former was just above the hole exposing the carbon in the latter. On striking an arc, bubbles of water vapor rise with a hissing sound. These bubbles also carry with them vapors of the substance as shown by the fact that fine particles like little puffs of smoke with characteristic color come out and condense on the side of the beaker (or the vessel containing water and in which the arc is immersed) as small drops, if the depth of water above the arc be not too great. The outer layer of the bubbles condenses and in some cases forms a skin; when the bubble rises just above the surface, it breaks—the gas included within it goes away as a little puff of smoke.

In this way it is possible to obtain dispersions of S, Se, P, dibenzyl and β -naphthol.

When the arc is struck, the carbon electrodes become enormously heated. The distance between the two electrodes can be easily regulated so that

it is possible to strike an arc with one just above and very near the coating, which becomes very much heated and the processes described previously take place. By a little practice the arc can be struck in the desired way.

Non-conducting substances were chosen to exclude any possibility of their taking part in the arc. Most organic substances are decomposed, however, at the high temperature of the arc, so very few of them may be used. It seems that both sulfur and selenium decompose water at the high temperature; these colloidal solutions show slight acid taste.

Sulfur, selenium, and phosphorus give good results. The deposit of phosphorus on carbon was obtained with white phosphorus melted under hot water. The low melting point of phosphorus presents some difficulties; the deposit melts and falls off to the bottom of the vessel when the arc is struck; but by repeated treatment of the same sample, fair yields are obtained. Another inconvenience is that the whole of the substance vaporized cannot be condensed completely under water, as part of it passes off as a vapor and another part condenses as a thin skin on the side of the beaker. With a small current density the yield is better. Since the liquid becomes hot during the experiment, it is better to cool the water with a freezing mixture.

In all cases "conductivity" water was used. With previously cooled water and with a current of 0.6 ampere good results are obtained in the case of selenium. The selenium sol improves on standing; this may be attributed to the oxidation of H_2Se by the atmospheric oxygen. If a little dilute nitric acid is added the effect is instantaneous. The sol is of brown color and is fairly stable.

Generally, when the sol is just prepared and is not disturbed, the upper part of the vessel contains the concentrated sol with the deep brown color.

All of these sols show the Tyndall phenomenon, a homogeneous cone of light being visible in all cases and they are fairly stable. The cone breaks up and finally disappears on the addition of electrolytes (*e. g.*, ZnSO_4 , BaCl_2 , etc.).

Also some observations were carried out with cadmium, mercury and copper.

Cadmium.—A deposit of the metal was made as usual on one of the carbon electrodes with a small hole exposing the carbon.

If the arc strikes directly on the metal, a green color is visible, but if it strikes on the carbon no color is noticeable. Little puffs of smoke containing particles of cadmium come out as in the case of sulfur. The hot cadmium reacts with water and some hydroxide is formed from the metal.

This sol being unstable, soon coagulates; the precipitate is found to consist of a mixture of cadmium and its hydroxide. Copper also behaves

similarly, the sol is unstable and the precipitate is a mixture of metallic copper and carbon.

It may be prepared by placing a carbon electrode, on which the deposits of the above substances were made, be fitted with a platinum cup as shown in the figure and mercury placed in it, then on lighting an arc between the mercury and the carbon electrodes, a copious formation of the sol of mercury is observed. This sol has a grayish color and is not brown as observed by Lottermoser.¹

The sol is quite stable. On the addition of hydrochloric acid, there is a precipitate, which does not dissolve in excess of concentrated hydrochloric acid, even on long standing and vigorous shaking. The filtrate also does not give any test of mercury salts. Evidently, colloidal solution of mercury is obtained in a state of great purity. The sol is charged negatively, as shown by its migration in an electric field.

This method is very rapid and gives very good yield with mercury, and is also very convenient.

The works of Traube-Mengarini and Scala² and Masamichi Kimura³ show that heat alone may lead to the formation of sols. While trying to prepare a sol of α -naphthol or of mercuric iodide by the first method, it was observed that both substances have appreciable solubilities at the boiling temperature of water. Now if such a solution be rapidly cooled by immersing a test tube containing the liquid in a freezing mixture of ice and common salt, a suspension of small crystals resembling a sol is formed. The sol is not so fine as those obtained by chemical methods, but it resembles ordinary sols in its behavior towards electrolytes. Thus the thermal effect may be conceived to be due to the solubility of the substance at the high temperature of the experiment.

The conditions of these experiments being such that a rapid fall from a high to a low temperature takes place, we may have a release of supersaturation in the form of fine particles, resulting in a sol.

Though such an explanation may be applied to special cases, it cannot explain all cases in general, since it depends on the specific nature of the substance and the medium.

The process of sol formation by the electric method is that as already stated, under the intense heat of the arc discharge, the electrodes volatilize and subsequently, being condensed, form sols.

Many metals react very rapidly at this high temperature with water and although the substances are very rapidly cooled, yet there is time for their action on water to take place. This is shown by the fact that

³ *Mem. Coll. Sci. Eng. Kyōtō*, **5**, 211 (1913).

the unstable sol of copper or cadmium consists of a mixture of the metal and the hydroxide.

It has been found out that the sol, when shaken with benzene, is divided into two parts, the hydroxide goes to the benzene layer while the metal remains in the aqueous layer. Copper sol prepared by Bredig's method was observed to be a mixture of the metal and the hydroxide. Blake¹ has observed that silver sol by Bredig's method reacts alkaline. In this case the particles consist mainly of the free metal but the little silver oxide (Ag_2O) present is sufficient to produce a red coloration with phenolphthalein, since silver hydroxide (AgOH) is a strong base.

The stability of metal sols prepared by these methods in water can be easily understood if we view it in the light of the above remarks. We know that sols of Au, Pt, Ag, etc., are only stable in water when prepared by electric methods, whereas those of more electropositive metals are unstable. In the case of Au, Pt, Hg and Ag, there is very little or no chemical action between the metals and water, so that the sol obtained consists entirely of metallic particles as shown by analysis.

In the cases of Cu, Cd, etc., we have a mixture of metal and its hydroxide due to chemical action with water.

Now the colloidal metallic hydroxides show electric migration to the cathode and hence are positively charged, the opposite is the case with the metallic particles. As a consequence, a colloidal solution of the one precipitates that of the other. This seems to be the explanation of the varying stability of different metallic sols in water prepared by these methods.

It is seen that a silver sol prepared by Bredig's method is fairly stable, though it has been found to be alkaline to indicators. The very small amount of Ag_2O formed remains completely in the state of ordinary solution and not as a sol, since no trace of alkali or Ag_2O is obtained in the coagulum produced by neutral electrolytes. It is well known that alkalis in very small concentrations stabilize a metallic colloidal solution and hence the small amount of alkali due to the solution of silver hydroxide makes the silver sol more stable. Consequently, the foregoing explanation can be consistently applied in the study of the stability of metallic colloidal solutions in general prepared by electric methods in water.

In conclusion, it may be stated that the high temperature of the arcing electrodes may explain the formation of sols simply as a thermal process.

My best thanks are due to Professors Rây and Bhaduri.

THE DETECTION OF BROMIDES IN THE PRESENCE OF THIOCYANATES, CYANIDES AND FERROCYANIDES.

By LOUIS J. CURTMAN AND ALAN G. WIKOFF.

Received December 4, 1914.

It was found some two years ago in this laboratory that the presence of thiocyanates interfered with the test for bromides by the chlorine-water method. While this investigation was in progress, Guareschi¹ published a method for overcoming this interference. His procedure, however, requires special apparatus and does not provide the means of roughly estimating the quantities of bromides present. It was, therefore, thought worth while to continue our work, the object of which was to determine the extent of this interference and to devise a simple and rapid method for overcoming this difficulty in the detection of bromides. Finding that cyanides and ferrocyanides also interfere, this investigation was extended to include these acid radicals. Ferricyanides do not interfere, it being possible to detect easily one milligram of bromine as potassium bromide in the presence of 500 mg. of ferricyanide by means of chlorine water.

Determination of the Interference.—Chlorine water saturated at room temperature was employed throughout this work and was kept in small glass-stoppered bottles of amber-colored glass. In making the tests, precautions were taken to maintain its strength by not allowing the bottle to stand open for any considerable length of time. In determining the amount to be used, it was found that with 3 drops of chlorine water, an excellent test was obtained with 1 mg. of Br as KBr, which was not appreciably improved by the further addition of a drop or two. It was also found that three drops of chlorine water gave a good test with 20 mg. of Br as KBr, although in this case all the bromine was not liberated. For the extraction of the liberated bromine, carbon disulfide was chosen as the solvent.

The general procedure was as follows: From a buret a definite volume of a standard potassium bromide solution was run out into a test tube. To this were added successively one drop of 10% hydrochloric acid, a definite volume of a standard solution of the potassium salt of the interfering acid, 0.5 cc. of carbon disulfide, and sufficient distilled water to make the volume up to 5 cc. Three drops of saturated chlorine water were then introduced and the mixture shaken. The results are shown in the tables.

All these tests were repeated with the same results. It is evident from an examination of the tables that thiocyanates offer the greatest and ferrocyanides the least interference.

¹ *Atti. accad. sci. Torino*, 49, 15-21; *C. A.*, 8, 1938.

TABLE I.

Interference of Thiocyanates.

0.25 mg. CNS.	Test.	0.20 mg. CNS.	Test.	0.15 mg. CNS.	Test.
1 mg. Br	Negative	10.0 mg. Br	Faint	1.0 mg. Br	Good
5 mg. Br	Negative	1.0 mg. Br	Faint	0.5 mg. Br	Fair
20 mg. Br	Negative	0.5 mg. Br	Very faint (limit)	0.3 mg. Br	Faint
				0.1 mg. Br	Very faint (limit)
				0.05 mg. Br	Negative

TABLE II.

Interference of Cyanides.

1 mg. CN. Test.	0.8 mg. CN. Test.	0.3 mg. CN. Test.	0.1 mg. CN. Test.
1 mg. Br Neg.	1.0 mg. Br Faint	1.0 mg. Br Good	1.0 mg. Br Excel.
5 mg. Br Neg.	0.5 mg. Br Very faint	0.5 mg. Br Fair	0.5 mg. Br Good
10 mg. Br Neg.	(limit)	0.4 mg. Br Fair	0.1 mg. Br Faint
20 mg. Br Neg.		0.2 mg. Br Faint	0.05 mg. Br Limit
		0.1 mg. Br Negative	

TABLE III.

Interference of Ferrocyanides.

4.0 mg. Fe(CN) ₆ ^{iv} . Test.	3.5 mg. Fe(CN) ₆ ^{iv} . Test.	3 mg. Fe(CN) ₆ ^{iv} . Test.	2.0 mg. Fe(CN) ₆ ^{iv} . Test.
1 mg. Br Neg.	1.0 mg. Br Faint	1.0 mg. Br Fair	1.0 mg. Br Fair
5 mg. Br Neg.	0.5 mg. Br Faint	0.5 mg. Br Fair	0.5 mg. Br Fair
10 mg. Br Neg.	0.4 mg. Br Very faint	0.4 mg. Br Fair	0.3 mg. Br Faint
20 mg. Br Neg.	0.3 mg. Br Negative	0.3 mg. Br Faint	0.1 mg. Br Very faint
		0.2 mg. Br Negative	(limit)

The above results may be accounted for on the supposition that the chlorine water exercises a selective action, oxidizing the interfering substance first before liberating the bromine from the bromide. Thus in Table I we see that the 3 drops of chlorine water added were sufficient to oxidize 0.15 mg. of CNS and still leave sufficient chlorine to liberate the bromine as indicated; while when 0.20 mg. CNS were present there was only a very small amount of chlorine left after the CNS had been oxidized, and hence the tests were faint. With 0.25 mg. CNS all the chlorine was consumed, and hence it was impossible to detect the bromine, however great it might be. If this theory be true, it should be possible by the continued addition of chlorine water to provide an excess over that required to oxidize the interfering substance and thus obtain a positive test in those cases where negative results were obtained with a limited amount of chlorine. This conjecture is confirmed only to a limited extent by the experimental evidence; for it was found that there is a limit in this case beyond which no amount of chlorine water will produce a positive result.

A determination of the limits was made by ascertaining in what amounts of interfering substances 1 mg. of bromine could be detected by the repeated additions of chlorine water, adding the latter 3 drops at a time and shaking after each addition.

TABLE IV.
3-5 cc. Chlorine Water.

1 mg. Br.		1 mg. Br.		1 mg. Br.	
10 mg. CNS	Negative	10 mg. CN	Negative	40 mg. $\text{Fe}(\text{CN})_6^{\text{iv}}$	Negative

2 mg. CNS	Fair	4 mg. CN	Faint	20 mg. $\text{Fe}(\text{CN})_6^{\text{iv}}$	Good
1 mg. CNS	Good	2 mg. CN	Fair	10 mg. $\text{Fe}(\text{CN})_6^{\text{iv}}$	Very good
		1 mg. CN	Good		

After much experimentation the following procedure was devised for the detection of bromides in the presence of thiocyanates, cyanides and ferrocyanides, based upon the precipitation of the respective radicals as cuprous salts in presence of sulfurous acid.

Method.—The solution to be tested, which should be neutral or slightly acid with sulfuric acid, is treated with 15 cc. of a saturated solution of SO_2 (this amount has been found by experiment to be sufficient to insure the precipitation of 500 mg. of CNS, CN or $\text{Fe}(\text{CN})_6^{\text{iv}}$ as their cuprous salts). The solution is now heated just to boiling, and while hot it is treated with constant stirring with 2 *N* CuSO_4 solution, which should be slowly run out from a buret or dropping funnel. Enough CuSO_4 must be added to insure an excess, shown by the blue color of the supernatant liquid. (In the presence of CNS a green liquid indicates insufficient H_2SO_3 and more must be added until the solution becomes blue. This is important since the green solution still contains CNS which has not combined with the copper and which, therefore, will interfere with the subsequent test for bromine.) Filter while hot, wash twice with distilled water, adding the washings to the main filtrate contained in an Erlenmeyer flask. Boil down the filtrate to about 5-10 cc. (This removes the excess of SO_2 and reduces the volume so that the final test may be made in a test tube. A slight white precipitate may form during this operation but may be disregarded.) Cool the contents of the flask¹ and pour into a test tube. Rinse the flask with 3-4 cc. distilled water and add to the liquid in the test tube. Add 1 cc. of 3 *N* H_2SO_4 , 1 cc. 1% KMnO_4 , and shake.² Now add not more than 0.5 cc. CS_2 and shake. A yellow color in the CS_2 layer proves the presence of Br.

The acid and KMnO_4 are added and shaken first in order that the CS_2 may not be in contact with the KMnO_4 any longer than is necessary, since they react with the formation of a small amount of MnO_2 which with vigorous shaking may dissolve in the CS_2 , yielding a color indistinguishable from that given by small amounts of Br. An excess of CuSO_4 is not ob-

¹ This may be easily accomplished by holding the flask under the tap of running cold water.

² Dilute HCl and Cl water may be used instead of the H_2SO_4 and KMnO_4 ; but the former has the disadvantage that the solution cannot subsequently be tested for chlorides.

jectionable since CuSO_4 in the presence of KMnO_4 liberates all the Br from KBr .¹

The following tests show the reliability of the method:

TABLE V.

No.	Mg. Br.	Mg. CNS.	Mg. CN.	Mg. $\text{Fe}(\text{CN})_2$ dv.	Results.
1	0.0	250	Absolutely no color
2-5	1.0	250	Negative
6-7	1.5	250	Fair
8-16	2.0-3.0	250	Good
17-20	4.0-10.0	250	Strong color
21-25	2.0	500	Good
26	4.0	500	Excellent
27	1.0	...	500	...	Negative
28-30	2.0	...	500	...	Excellent
31	1.0	500	Negative
32-34	2.0	500	Excellent
35	2.0	200	150	150	Good
36	2.0	300	100	100	Good
37	2.0	100	200	200	Good
38	2.0	400	50	50	Good

The average time required for the completion of a test was 15 min.

Summary.

1. Attention has been called to the interference of thiocyanates, cyanides and ferrocyanides in the detection of bromides by the ordinary methods.
2. The interference offered by each of these substances has been determined.
3. A rapid method has been devised which is capable of detecting 2 mg. of bromine in the presence of 500 mg. of each of the interfering substances.
4. Numerous test experiments show the method to be trustworthy.

NEW YORK, N. Y.

ON FRACTIONAL DISTILLATION WITH REGULATED STILLHEADS.

[FIRST COMMUNICATION.]

CASES IN WHICH THE BOILING-POINT CURVE PASSES THROUGH A MAXIMUM OR A MINIMUM.

BY M. A. ROSANOFF AND C. W. BACON.

Received December 31, 1914.

Section 1. Introductory.

A recent joint communication² outlined a theory of fractional distillation based on a new relationship between the slopes of the total pressure curve and the relative compositions of the liquid mixtures and the corresponding vapors. In the mathematical treatment it was assumed that

¹ Prescott and Johnson's "Qualitative Analysis," p. 346.

² Rosanoff, Bacon, and Schulze, *THIS JOURNAL*, 36, 1993 (1914).

the process involved no reflux condensation whatever, that is, that the vapors escaped without any part of them undergoing liquefaction on the way and returning to the still. This is the simplest thinkable type of distillation, and, therefore, of unquestionable interest theoretically. As an actual means of separating the constituents of liquid mixtures, whether for scientific or industrial purposes, it is not used. For hundreds of years¹ chemists have purposely employed partial reflux condensation to produce as wide a difference between the distillate and the residue in the still as can be conveniently brought about in a single operation, and thus increase the efficiency of fractional distillation.

F. D. Brown² differentiates two processes by which partial reflux condensation is brought about in the various forms of apparatus in general use. To quote from Brown's own statement: "Though differing much in detail, they [the various apparatus] are all designed to subject the mixed vapors to one or both of two well-defined processes, which may be termed respectively *washing* and *cooling*. In the process of *washing*, the mixed vapors issuing from the still are made to pass through several layers of liquid obtained by their own partial condensation, they are thus *washed* by these successive layers, and it is supposed that the vapor of the liquid of highest boiling point is partially removed by this process, which results, therefore, in a distillate containing more of the liquid of lower boiling point than would be obtained by simple distillation. In the process of *cooling*, the mixed vapors are partially condensed, either by allowing radiation to take place, or by passing them through a coil kept at a given temperature; the liquid of highest boiling point suffers, of course, the most condensation, and runs back into the still, a better distillate being thus obtained. With a view to learning whether these two processes of *washing* and *cooling* really differ in their effects, I have made the experiments now to be described."

In the present state of knowledge no experiments would be necessary to prove that partial condensation by washing and partial condensation by cooling are different processes. Thus numberless cases might be specified in which a colder mixed vapor would be partially condensed by passing through a *hotter* mixed liquid. In such cases "*cooling*" is out of the question, yet partial condensation would take place, due to what Brown calls the "*washing*" of the vapor. Brown demonstrated the difference between washing and cooling by fractionating mixtures of carbon disulfide and benzene under suitably varied experimental conditions. The results are summed up by his statement (p. 56): "These distillations prove conclusively that the processes of *washing* and of *cooling* are not identical."

¹ See Young, "Fractional Distillation" (London, 1903), p. 154.

² Brown, *Trans. Chem. Soc.*, 37, 49, 50 and 56 (1880).

In the stillheads or columns generally used, the processes of washing and cooling are more or less intimately combined, for the ascending vapor is not only washed, but also cooled, by the reflux condensate. Nevertheless, it is certain that the main process by which the efficiency of such apparatus is determined, is washing; and a vast majority of the patented improvements consist in the introduction of ingenious "traps" in which the vapors are thoroughly washed in pools of the reflux condensate. Where cooling devices proper are employed at all, they play a decidedly subordinate role.

That distillation depending principally, almost exclusively on cooling, may have important possibilities of its own, has long been suspected, and attempts have been made to rationalize fractional distillation by the use of a non-washing stillhead kept at a constant temperature. The first to employ such a stillhead practically (in the fractionation of petroleum, coal tar, and other mixtures) was C. M. Warren, of Boston, who believed that the method promised results of great value.¹ The first to investigate the working of a regulated stillhead systematically was F. D. Brown,² who improved Warren's stillhead and made extensive observations on the effect of cooling a saturated binary vapor to a given constant temperature. Brown sums up his results in the following important statement: "*In distillation with a stillhead maintained at a constant temperature the composition of the distillate is constant, and is identical with that of the vapour evolved by a mixture whose boiling point equals the temperature of the stillhead.*"

An attempt to utilize the regulated stillhead was also made by Lord Rayleigh.³ On the other hand, Carveth⁴ experimented with a combination of the washing and the cooling processes by filling a tin pipe condenser with intercepts and maintaining the pipe at a constant temperature.⁵ Finally, Sydney Young and Thomas⁶ obtained valuable results by connecting in series a dephlegmator (washing column) and a regulated temperature stillhead, as is frequently done in the industries. But these studies have thrown no new light upon the regulated stillhead theoretically.

In course of the past five years, the working of the regulated stillhead has been fully reinvestigated by one of us with several collaborators. It was found that Brown's law requires serious modification, and that only in its true form can it serve as the basis of a rational, almost ideal, process of fractional distillation, such as the previous investigators have searched for in vain. The modified law, and the process of distillation based upon

¹ Warren, "Memoirs of the American Academy," New Series, 9, 121 (1864), and *Ann.*, 4 (Supplementband), 51 (1865).

⁴ Carveth, *J. Phys. Chem.*, 6, 253 (1902).

⁵ An arrangement similar in principle had already been employed by Perrier.

⁶ Young and Thomas, *J. Chem. Soc.*, 71, 440 (1897).

it, will be discussed in a series of communications to which the present paper may serve as an introduction.

The main object of this present communication is to point out how the regulated stillhead should be expected to function in those numerous cases in which the boiling-point curve passes through a maximum or a minimum; in which, therefore, there may be *two* mixtures boiling at one and the same temperature: in the words of Brown's law, *two mixtures* "whose boiling point equals the temperature of the stillhead."

Section II. Brown's Law in the Cases under Consideration.

Let us assume for the present that Brown's law is true in its original form, as expressed above. And considering a simple case, like that of carbon disulfide and carbon tetrachloride, where the boiling points of all mixtures are intermediate between those of the isolated components, let the temperature of a regulated stillhead be made equal to the boiling point of the more volatile component. Then, by the original Brown law, no matter what the composition of the mixture boiling in the still, the escaping vapor should consist almost entirely of that component.

On the other hand, suppose we are dealing with a pair of substances whose boiling-point curve passes through a minimum. And, while any given mixture of the two is boiling in the still, let the stillhead, originally cold, be heated to the boiling temperature of the most volatile mixture (*i. e.*, the one having the minimum boiling point). The vapor from such a mixture has the same composition as the mixture itself, and, therefore, if Brown's law is correct, that should also be the composition of the escaping vapor, no matter what mixture is at any given instant boiling in the still. But next let us still further raise the temperature of the stillhead, and fix it at the boiling point of the more volatile component. Now the stillhead temperature is really equal to the boiling point of two different liquids: the more volatile component pure and a certain mixture. The vapors given off by the two liquids are, of course, different: in one case a single substance, in the other a mixture. Which of the two vapors will be escaping from the stillhead?

Brown's experiments with the pairs carbon disulfide-alcohol and carbon disulfide-ethyl acetate taught him that it is the *mixed* vapor that is produced invariably.¹ In the case of carbon disulfide and alcohol, keeping the stillhead at the boiling point of pure carbon disulfide, Brown obtained a uniform distillate containing about 87.3% of carbon disulfide. In the case of carbon disulfide and ethyl acetate, with the stillhead at the boiling point of pure carbon disulfide, he obtained a uniform distillate containing about 72.6% of carbon disulfide.

Brown says nothing as to the effect of keeping the stillhead at temperatures *intermediate* between the boiling point of the most volatile mixture

¹ Brown, *J. Chem. Soc.*, 39, 529 (1881).

and that of the isolated more volatile component—temperatures at which two different mixed vapors should be expected according to his law. Nor does he refer at all to those cases in which the boiling-point curve passes through a maximum, and in which, therefore, two different mixed vapors might be expected at any stillhead temperature intermediate between the boiling point of the least volatile mixture and that of the isolated less volatile component. He evidently felt that an experimental elucidation of the subject would be of value; for he expresses the hope of returning to the problem in a future communication. This he never did. Nor is the subject at all mentioned in the more recent monograph literature on heterogeneous equilibria or fractional distillation.

At the present time, especially if we employ the form of diagram (see Fig. 1) in which both the boiling-point curve and the dew curve (vapor-composition curve) are plotted with respect to abscissae representing the composition of liquid mixtures, the question as to which of the two possible

Fig. 1.

mixed vapors should be expected in accordance with Brown's law, presents no real difficulty. Since distillation with a regulated stillhead cannot affect the composition of a mixture of maximum or minimum boiling point, it is almost obvious that in all cases of the type in question the diagram should be divided into two parts by a straight line perpendicular to the composition-axis and passing through the maximum, or the minimum, of the boiling-point curve, and each part should be considered as an independent diagram by itself. The composition of the resulting vapor would then appear to depend upon whether the composition of the liquid in the still is comprised in the right-hand or the left-hand part of the diagram. For example, in our Fig. 1, which pictures the case of carbon disulfide and acetone, let the stillhead temperature be at the height of the lines aa' , $b'b$. Then it is obvious in the first place that the stillhead will have no effect at all if the liquid in the still corresponds to any point

lying between a and b ; for any such liquid would boil below the temperature of the stillhead, and a hot stillhead cannot condense a cold vapor. But further we should expect that if the composition of the liquid boiling in the still is represented by a point lying to the left of a , the stillhead will deliver a uniform vapor of the composition a' ; if the liquid boiling in the still has a composition lying to the right of b , then the stillhead, *at the same temperature as before*, will yield a uniform vapor of the composition b' .

Trustworthy as these theoretical expectations appear, it nevertheless seemed desirable to carry out a series of experiments, to obtain a practical demonstration of their correctness. The results are reproduced below.

Section III. The Apparatus.

Our apparatus (Fig. 2) was similar in principle to the one employed, in a former study, by Rosanoff, Lamb, and Breithut.¹ It consisted of a large double-walled cylinder of tinned copper, without top or bottom, fastened within a cylindrical tank full of water. The closed annular space between the walls of the copper cylinder was connected with the still below by a brass pipe passing through the bottom of the outside tank, near the rim. A similar pipe, serving as a delivery tube, and passing through the side of the outside tank, near the top, connected the annular space with a condenser. The lower edge of the double-walled cylinder was in a plane slanting downward toward the still, to permit any condensate within the annular space to flow back without forming a pool at the bottom. The water in which the double-walled cylinder was immersed was kept in vigorous motion by a pair of horizontally revolving fans whose diameter was little less than the internal diameter of the copper cylinder, and which acted with the effect of an Archimedes screw. In this manner uniform temperature was secured throughout the tank, an electric regulator maintaining the temperature of the bath constant within $\pm 0.02^\circ$. The greatest height of the double-walled cylinder was 76 cm.; its smallest height was 70 cm.; the mean diameter was 25 cm.; and the annular space between the walls was 0.95 cm. wide. It may be positively stated that a stillhead of this form is greatly superior to the coil condensers used by previous investigators.

The substances used were purified, and our consecutive distillates were analyzed, in the manner described in a former communication.²

And first of all, the efficiency of our regulated stillhead was subjected to test in the case of carbon disulfide-carbon tetrachloride, which is not complicated by either a maximum or a minimum in the boiling-point curve. A mixture containing slightly over 26% of carbon disulfide was introduced

¹ Rosanoff, Lamb, and Breithut, *THIS JOURNAL*, 31, 454 (1909); *Z. physik. Chem.*, 66, 356 (1909).

² Rosanoff, Bacon and White, *THIS JOURNAL*, 36, 1803 (1914).

into the still, and the temperature of the stillhead was maintained constant at $59.82^{\circ} \pm 0.02^{\circ}$. Theoretically, *i. e.*, according to Brown's law, the

Fig. 2.

distillates were expected to contain 60.8% CS_2 . Seven consecutive fractions were actually found to contain 60.8, 60.7, 60.7, 60.5, 60.7, 60.5,

60.7, 60.7, and 60.7% of carbon disulfide, respectively. The reliability of the apparatus was thus demonstrated.

Section IV. Results.

Case 1. Carbon Disulfide and Acetone.—In this case the boiling-point curve passes through a *minimum*.¹

In a first experiment a mixture containing only a small percentage of acetone was introduced into the still. The temperature of the stillhead was kept constant at $40.02^{\circ} \pm 0.01^{\circ}$. Seven consecutive fractions of the distillate contained: 75.2, 75.2, 75.1, 75.1, 75.1, 75.1, and 75.1 molar per cent. of carbon disulfide, respectively.

In a second experiment, we introduced into the still a mixture containing only 29% CS_2 (a composition lying within the left-hand part of the diagram). The temperature of the stillhead was again kept at $40.02^{\circ} \pm 0.01^{\circ}$. Yet this time fifteen consecutive fractions of the distillate were found to contain, respectively, 55.4, 55.3, 55.4, 55.4, 55.4, 55.3, 55.4, 55.4, 55.4, 55.4, 55.4, 55.2, 55.4, 55.3, and 55.3 molar per cent. of carbon disulfide.

Case 2. Ethyl Iodide and Ethyl Acetate.—In this case again the boiling point passes through a *minimum*.

In a first experiment a mixture containing only a small percentage of ethyl acetate was introduced into the still, and the temperature of the stillhead was fixed at $71.22^{\circ} \pm 0.02^{\circ}$. Four consecutive fractions of the distillate contained 89.9, 89.3, 89.2, and 89.1 molar per cent. of ethyl iodide, respectively.

In a second experiment a mixture of roughly equal parts of the two components was introduced into the still. The temperature of the stillhead was the same as in the first experiment. But this time four consecutive fractions of the distillate were found to contain, respectively, 49.4, 49.3, 48.9, and 48.9 molar per cent. of ethyl iodide. In this case the uniformity of the distillates was not as perfect as before. Nevertheless the two experiments illustrate the question involved sufficiently well.

Case 3. Chloroform and Acetone.—In this case the boiling-point curve passes through a *maximum*.

Two experiments again were performed. In the first, a mixture containing roughly 6% of acetone (a composition lying to the right of the maximum) was introduced into the still. The temperature of the stillhead was fixed at $62.02^{\circ} \pm 0.01^{\circ}$. Six consecutive fractions of the distillate were found to contain, respectively, 92.4, 92.4, 92.4, 92.5, 92.3, and 92.3 molar per cent. of chloroform.

In the second experiment the mixture originally introduced into the still contained something over 40% CHCl_3 (a composition lying to the left of the maximum). The temperature of the stillhead was again maintained

¹ This case is illustrated by Fig. 1, in which, however, the abscissae represent *weight per cents*.

at 62°. This time, however, six fractions of the distillate were found to contain, respectively, 30.8, 30.8, 30.9, 30.8, 30.9, and 30.9 molar per cent. of chloroform.

As already stated, changes in Brown's law itself will be proposed in communications to follow. Here we would again express our thanks to the Rumford Committee of the American Academy for a grant in aid of our researches.

THE MEASUREMENT OF VAPOR PRESSURE LOWERING BY THE AIR SATURATION METHOD.¹

BY EDWARD W. WASHBURN AND EDWARD O. HEUSE.

Received December 16, 1914.

1. Introduction.

The importance of having a reasonably accurate method for investigating the molecular character of aqueous solutions over a considerable concentration range and at a constant temperature led to an attempt to improve the vapor pressure method so that it might be employed for this purpose. The experimental work in connection with the problem was begun in 1909 by Mr. H. B. Gordon. He was able to show that the method could be made to give the desired accuracy and in addition to building and testing the apparatus he also measured the vapor pressure lowering of several aqueous solutions. The results of his work together with a comparative discussion of previous investigations in the same field were printed and distributed in 1912 in the form of a Doctor's Thesis,² but were not formally published. In September 1912 the experimental work was taken up by Mr. E. O. Heuse and is being carried on by him at the present time. A description of the theory of the method together with some of the results obtained was presented at the Chicago meeting of the American Physical Society, November, 1914, and published in abstract in the *Physical Review*.

The appearance of a recent paper by Frazer and Lovelace³ on an improved *static* apparatus for measuring vapor pressure lowering seems to make it worth while to publish a description of our apparatus and method at this time, for purposes of comparison, postponing until later

¹ This paper is an abstract of a thesis presented to the Graduate Faculty of the University of Illinois in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1914.

the presentation and theoretical interpretation of the vapor pressure data which have been collected with it.

2. Outline of the Method.

The dynamic or air-saturation method when employed for the purpose of measuring the difference between the vapor pressure (p_0) of a solvent and that (p) of a solution has usually been carried out by determining each of these quantities separately and then subtracting one from the other. This procedure gives a very low degree of accuracy on the vapor pressure lowering, the chief sources of error being (1) in the measurement of the quantity of air aspirated and (2) in maintaining the average temperature of two successive experiments sufficiently constant. The obvious modification which is necessary in order to eliminate these two sources of error is to pass the same air (whose quantity, therefore, need not be known) over the solution and the solvent in succession, each liquid being contained in a suitable "saturator" and both saturators being placed beside each other in a well stirred thermostat. Then one may either determine the losses in weight of the two saturators by weighing them before and after the experiment, as in the method of Ostwald-Walker or one may absorb the moisture in absorbers of such form and size that they can be accurately weighed. The former method has been successfully carried out by Berkeley, Hartley and Burton¹ with aqueous solutions at 0°. The latter method seemed preferable to us, however, because it involved no change in the concentration of the solution during the run and the volume of air and its rate of flow could be made as large as desired, since there was no necessity of employing a small and compact saturator as is the case when the saturator has to be weighed.

Our apparatus, therefore, has been constructed so as to embody the advantages of the differential procedure first used by Ostwald and Walker with those of the absorption method which has been employed by most investigators in this field. The type of absorber which we have employed coupled with the comparatively high rate of aspiration used necessitates the use of small differential manometers for the purpose of measuring the fall in pressure through the apparatus. With a different type of absorber cooled with liquid air, these manometers could probably be dispensed with.

3. Calculation of the Relative Vapor Pressure Lowering.

The following method of computing the results of an experiment conducted as outlined above is applicable to moderate temperatures: At high temperatures, where the deviation of saturated water vapor from Boyle's law is large, corresponding modifications must be made in the method of calculation, but these will not be entered into here.

¹ Berkeley, Hartley and Burton, *Phil. Trans.*, (A) 209, 177 (1909).

The mass, m , of water necessary to saturate a volume, v , of air in order to bring it into equilibrium with a liquid whose aqueous vapor pressure is p is expressed by the equation

$$m = Kpv \quad (1)$$

where K is a proportionality constant. In the method just outlined the same air is passed through both saturators and hence the volume emerging from a saturator will vary inversely as the partial pressure of the air in that saturator. Obviously, this is in each case the atmospheric pressure diminished by the vapor pressure of the liquid with which the air is in equilibrium and by the difference between the total pressure within the saturator and the atmospheric pressure. It therefore follows that

$$\frac{v_1}{v_2} = \frac{B - p_2 - \Delta P_2}{B - p_1 - \Delta P_1} \quad (2)$$

where the subscripts indicate whether the quantity is measured at the outlet of the first or the second saturator of the train. B is the barometric pressure and ΔP the difference between this pressure and that within the saturator as measured by a differential manometer.

From (1) it follows that the ratio of the masses of water absorbed by the two absorbers will be

$$\frac{m_1}{m_2} = \frac{p_1 v_1}{p_2 v_2} \quad (3)$$

If the second saturator contains pure water ($p_2 = p_o$) and the first saturator an aqueous solution ($p_1 = p$), we have from (2) and (3)

$$p = \frac{m p_o (B - \Delta P_1)}{m_o (B - p_o - \Delta P_2) + m p_o} \quad (4)$$

Dividing both sides of Equation 4 by p_o , subtracting each side from unity, expressing the result in the fractional form and collecting terms, we have

$$r = \frac{p_o - p}{p_o} = \frac{(m - m_o)p_o + m_o(B - \Delta P_2) - m(B - \Delta P_1)}{(m - m_o)p_o + m_o(B - \Delta P_2)} \quad (5)$$

Putting $m_o - m = D_m$ and $\Delta P_2 - \Delta P_1 = D_p$ gives

$$r = \frac{p_o - p}{p_o} = \frac{D_m(B - \Delta P_1 - p_o) - m_o D_p}{m_o(B - \Delta P_2) - D_m p_o} \quad (6)$$

This is the expression for $\frac{p_o - p}{p_o}$ in terms of the quantities which are directly measured in the experiment. In order to make clear the relative importance of the different terms in this expression and their influences upon the accuracy of the result, we will substitute typical values for them as obtained in an actual experiment in which the solution employed was a molal solution of cane sugar. This gives

$$r = \frac{p_0 - p}{p_0} = \frac{0.2401(749.01 - 0.24 - 23.71) - 11.7458 \times 0.050}{11.7458(749.01 - 0.29) - 0.2401 \times 23.71} = \frac{174.1 - 0.59}{8794.2 - 5.6} = \frac{173.5}{878.9} = 0.0197. \quad (7).$$

Suppose for example that we desire an accuracy of 1% in value of r . Of the terms appearing in the denominator the last one, $D_m p_0$, is practically negligible in comparison with the first and in the first term the quantity ΔP_2 is practically negligible in comparison with B . At most an accuracy of a few tenths of a mm. in measuring ΔP_2 would be ample, and an accuracy ten times as great as this is easily attained. The degree of accuracy with which the denominator of Equation 6 is known depends, therefore, practically upon the accuracy with which m_0 and B can be measured, and it is clear that both of these quantities can be easily measured with 10 or 100 times the necessary accuracy. As far as the terms in the denominator are concerned we may, therefore, conclude that the errors involved in their measurement will not have any appreciable influence upon the accuracy of the result.

Turning to the numerator we note that the second term, $m_0 D_p$, is very small in comparison with the first, and that at most an accuracy of 0.05 mm. in the measurement of D_p would be ample. This degree of accuracy, and more, can be easily attained. In the first term of the numerator ΔP_1 is practically negligible while p_0 , the vapor pressure of the pure solvent at the temperature of the experiment, needs to be known with an accuracy of 7 mm. (i. e., 30%) if it is not to influence the accuracy of the result by more than 1%. In the case of water it is of course known with an accuracy 100 times greater than this and in any case its determination with the necessary degree of accuracy offers no difficulties. We may conclude, therefore, that the percentage accuracy of the result is almost entirely determined by the percentage accuracy attainable in the quantity D_m , that is, the difference in the increases in mass of the two absorbers and this difference is itself directly determined by placing the absorbers on the opposite pans of a sensitive balance and adding the necessary weights to produce equality. This difference can be determined to 0.1 or 0.2 mg. and in the example taken this would amount to less than 0.1%. Practically, however, the accuracy of the final result is not determined by the accuracy in measuring the actual difference D_m obtained but rather in insuring such perfect experimental conditions that the observed D_m shall correspond to the actual pressure difference within the required limits. As will be seen later the degree of concordance in duplicate experiments is more nearly 0.5% in the case of a molal solution.

From this discussion of the theory of the differential method the following facts are brought out, which distinguish it from most of the previous

attempts to determine the vapor pressure lowering of aqueous solutions by means of the dynamic or air-saturation method:

(1) It is not necessary to measure or to know even approximately how much air is passed through the system during the experiment, and its amount may, therefore, be made as large as desired.

(2) In order to measure the relative lowering of the vapor pressure the individual vapor pressures themselves are not required, except a very rough value of p_0 , the vapor pressure of the pure solvent, an accuracy of a few mm. in the value of p_0 being amply sufficient.

(3) Temperature variations¹ as great as 1° during the course of an experiment would not appreciably influence the result for solutions of moderate concentrations provided the thermostat is kept thoroughly stirred.

4. Description of the Apparatus.

General Arrangement.—In the apparatus now in use *three* saturators are employed in each experiment, the first and third containing pure water and the second the solution under investigation. The general plan of the apparatus is shown diagrammatically in Fig. 1.

Air, drawn by the constant level aspirator *B* passes first through the soda lime tube, *T*, and then into the presaturator, *PS*₁, where it is *saturated* with water vapor at about 50° . The air then passes down into the flask *F* which is immersed in the thermostat and here it deposits most of its excess of moisture and enters the first saturator *S*₁ of the train slightly supersaturated. On emerging from this saturator it is in equilibrium with water at 25° . It then passes out of the thermostat through the tube *C*₁, which is surrounded by a heating coil and is heated to a temperature of about 30° before it emerges from the thermostat. The warm air then passes at once through the absorber *A*₁ where all of the moisture is removed. The perfectly dry air then goes through a second presaturator, *PS*₂, containing water at 25° where it takes up the bulk of the moisture necessary to bring it into equilibrium with the solution in saturator *S*₂. After passing through this saturator and its absorber, *A*₂, the perfectly dry air then passes directly into the third saturator, *S*₃, which contains pure water. In the first and third saturators equilibrium is always approached from *opposite directions* and a valuable check upon experimental conditions is thus obtained.

¹ The temperature coefficient of $r = \frac{p_0 - p}{p_0}$ is $\frac{100 \, dr/dt}{r} = 100 (1 + 1/r)$

$\frac{L_D}{RT^2}$ per degree where L_D is the differential heat of dilution (heat absorbed) per mole of solvent. At 25° this becomes $\frac{100 \, dr/dt}{r} = 5.66 \cdot 10^{-4} (1 + 1/r) L_D$. Thus for a molal cane sugar solution L_D is about 2 cal. and $r = 0.02$. Hence the temperature coefficient of r for this solution is only 0.06% per degree.

The small differential manometers, M_1 , M_2 , M_3 connected (through stopcocks S_1 , S_2 , S_3 as shown) serve to measure the pressure differences Δp_1 , Δp_2 and Δp_3 , respectively, between the manometers under the

water of the thermostat are sealed glass joints, the whole apparatus being supported on a frame as shown in Fig. 2. The details of construction of the different parts follow.

The Saturators.—These are of the type devised by Berkeley and Hartley,¹ modified by the addition of the small bulbs at the ends as shown in Fig. 3 and Fig. 2. The horizontal tubes are filled about half full of

Fig. 2.

(Letters in parentheses refer to Fig. 1.) (1) Tubes leading to manometers. (2) Presaturator (PS_2) for solution. (3) Tube and heating coil (C_2). (6) P_2O_5 safety tube. (8) Saturator (Sa). liquid and then, as the platform on which the saturators are placed rocks slowly back and forth, the liquid flows from one end of the horizontal tubes to the other. The air which enters at the center of each horizontal tube passes around through

Fig. 3.

¹ Berkeley and Hartley, *Proc. Roy. Soc., (A)* **77**, 156 (1906).

first one vertical connecting tube and then the other as the saturator tips back and forth. The air never bubbles through the liquid at any point. The small bulbs in the vertical connecting tubes are for the purpose of breaking liquid films which sometimes form in the case of certain solutions. The saturator for the solution contains quartz beads which roll back and forth and aid in keeping the solution stirred.

The Absorbers.—The type of absorber used for removing and weighing the water is shown diagrammatically in Fig. 4. Most of the water is condensed in the flask, *F*, which is cooled by an ice bath in a silvered Dewar tube. The air then passes over concentrated sulfuric acid contained in the four tubes, *A*.

Fig. 4.

These tubes have a series of depressions or pockets (not shown in the figure) along the bottom for increasing the amount of sulfuric acid which they will contain. The two tubes, *P*, are about two-thirds filled with glass beads and phosphorus pentoxide and a removable pentoxide safety tube (not shown) completes the absorber and serves to prevent the diffusion of any moisture backward against the air current. The absorber is compactly built so that it will fit the pan of a sensitive balance. It is shown in position on the upper shelf of the support, at 13 in Fig. 2. About 25 g. of water can be condensed and absorbed in one absorber. The different absorbers are as nearly identical as possible in construction and when charged ready for use weigh about 300 g. each.

The Differential Manometers.—The small differential manometers, M_1 , M_2 , M_3 , shown in Fig. 1 are water manometers inclined at such an angle that 1 mm. of mercury is equivalent to 200 mm. of water. The angle of inclination was determined accurately by means of a cathetometer. The stopcocks which separate these manometers from the train are opened at intervals during the run and the readings of the manometers recorded.

When the experiment is proceeding properly these readings are practically constant throughout the run.

The Thermostat.—The apparatus and support as shown in Fig. 2 are immersed in a large water bath at such a depth that the three lower platforms and their saturators are completely covered. The whole support is then rocked back and forth on the axle (14, in Fig. 2) at the rate of four complete oscillations per minute. In addition to the stirring produced by this motion two powerful turbine stirrers and one propeller blade stirrer insure a uniform temperature throughout all parts of the thermostat. Three heaters symmetrically distributed and controlled by a hydrogen regulator served to keep the temperature constant.

With this arrangement the apparatus can be kept in continuous operation and as many runs as desired made with a given solution, the air current being interrupted only long enough to replace one set of absorbers by another. When a new solution is to be employed the apparatus is lifted out of the thermostat, the old solution removed with a pipet and the new one introduced. It is not necessary to take the apparatus apart for this operation. Previous to the first insertion of a weighed pair of absorbers in the train the air current is allowed to pass through the system for half an hour to insure equilibrium and proper working conditions. The barometer is read from time to time during the run. In one or two cases the occurrence of thunder storms during the run necessitated the use of a barograph record in finding the weighted time average of the barometric pressure during the run.

5. Testing the Apparatus.

One of the most satisfactory methods of testing the apparatus is to make a run with pure water in all three saturators and then compute the value of $r = \frac{p_0 - p}{p_0}$ by means of Equation 6. The result should of course be zero. In seven successive experiments of this kind in which only two saturators were employed Gordon found an average value¹ of 0.026 for 100 r . With the apparatus now in use this has been considerably reduced indicating a more perfect attainment of equilibrium between the liquid and gaseous phases during the passage of the air current. Some typical data of this kind are shown in Table I. When one recalls that the value of 100 r for a molal aqueous solution of a nonelectrolyte is about 2 it is evident that the residual errors indicated by the figures in the last column of Table I would tend to show that the error in measuring the vapor pressure lowering of a molal solution should not exceed one-fourth of 1% on the average.

6. The Vapor Pressures and Osmotic Pressures of Cane Sugar Solutions.

The Experimental Data.—In order that a check upon the reliability of the results obtained with our apparatus might be secured, some measurements were carried out with solutions of cane sugar for the purpose of securing a comparison with the accurate osmotic pressure data obtained by Morse. The sugar employed had been carefully purified and the measurements were made on a weight molal solution to which 0.1 of 1% of HgCl_2 was added. The results obtained are shown in Table II. The average percentage deviation of the individual results from the mean is 0.4% showing that reasonably *concordant* results can be obtained at this concentration. Their *accuracy* can be tested by calculating the corresponding values of the osmotic pressure and comparing with Morse's directly measured values for the same solution.

² $r = (p_o - p)/p_o$.

³ Because of the small value of m_o in this run, this value was given only half-weight in the calculation of the mean.

Osmotic Pressure and Vapor Pressure Lowering.—The osmotic pressure of a solution as directly measured in such experiments as those of Morse is defined by the equation

$$\pi' = P - 1 \quad (8)$$

where P is the pressure (in atmospheres) upon the solution when osmotic equilibrium is attained. The osmotic pressure thus defined is connected with the partial vapor pressure of the solvent by the purely thermodynamic relation,¹

$$\left(\frac{\partial p}{\partial \pi'}\right)_T = -\frac{\bar{V}}{v}, \quad (9)$$

where v is the specific volume of the saturated vapor at the temperature T , and \bar{V} , the "specific solution volume" of the solvent, is the increase in volume which occurs when 1 g. of the solvent is added to an infinite amount of the solution, under the pressure P .

For saturated water vapor at 25°, we may without appreciable error assume Boyle's law for the small pressure interval here involved and write

$$v = \frac{k}{p}. \quad (10)$$

The constant k is most accurately obtained from the thermodynamic relation

$$k = \frac{L_v p}{T(\partial p / \partial T)_p} \quad (11)$$

where L_v is the latent heat of vaporization. The best available data for water when substituted in this equation give a value of k which is not appreciably different from $RT/18$ which value we shall, therefore, employ.

\bar{V} , the specific solution volume of the solvent, will in general be a function of π' . It may be calculated for any solution which contains s per cent. of solute and has the density D_P , by means of the relation

$$\bar{V} = \frac{1}{D_P} + \frac{s}{D_P^2} \left(\frac{dD_P}{ds} \right) \quad (12)$$

For cane sugar solutions the evaluation of \bar{V} at 25° in terms of π would strictly require a knowledge of the proper compressibility coefficients of the solutions at this temperature. No such data seem to be available but by employing those of Tait² for 12.4° an approximate calculation of \bar{V} as a function of π' may be made. In this way we find the following values:

¹ This rigorously exact relation can be written down immediately with the aid of the perfect thermodynamic engine described in a previous paper (THIS JOURNAL, 32, 467 (1910)) giving a much shorter and more direct derivation than that given by Porter for the relation between these two quantities.

² Landolt-Börnstein tables.

π	0	8.44	16.93	22.16	26.52	atmospheres
\bar{V}	1.0029	1.0056	1.0034	1.0008	0.999	cc.

By integration between 0 and 27 atmospheres the average value of \bar{V} between these limits is found to be 1.003.

Equation 9, therefore, becomes

$$1.003 \, d\pi' = - \frac{RT}{18} \frac{dp}{p} \quad (13)$$

and on integration gives

$$\pi' = \frac{RT}{18.054} \left[\left(\frac{p_0 - p}{p_0} \right) + \frac{1}{2} \left(\frac{p_0 - p}{p_0} \right)^2 + \dots \right] \quad (14)$$

In Table III the values of π' calculated with this equation from the vapor pressure data of Table II are compared with the directly measured values of Morse. The agreement between the two is well within the experimental errors of the vapor pressure data and justifies the conclusion that the values obtained with our apparatus are correct within their own degree of precision.

7. Discussion of the Method.

The results obtained with our apparatus indicate that values of $\frac{p_0 - p}{p_0}$ of the order of magnitude of 0.02 can be measured with an accuracy of better than 0.5% in a 24-hour run. This seems to be about ten times better than the best values recorded for the dynamic method as usually carried out.¹

The experiments of Berkeley, Hartley and Burton,² however, who employed the differential method of Ostwald-Walker also gave closely concordant results. They worked with calcium ferrocyanide solutions in small saturators of the same general form as that shown in Fig. 3 and their method differed from ours only in the fact that the air entered the system perfectly dry and the losses in weight of the two saturators were determined by weighing them directly. It is difficult to directly compare the degree of accuracy which they obtained with that given by our ap-

¹ Cf. Gordon's discussion, *Loc. cit.*, p. 23.

² *Loc. cit.*

paratus because they worked entirely with stronger solutions and only two measurements are recorded for any one concentration. Their most dilute solution gave $\frac{p_0 - p}{p_0} = 0.032$, the two determinations differing by only 0.2%. Similarly for stronger solutions, the differences between the two determinations were for $\frac{p_0 - p}{p_0} = 0.054$, $d = 0.1\%$; for $\frac{p_0 - p}{p_0} = 0.065$, $d = 0.03\%$; for $\frac{p_0 - p}{p_0} = 0.084$, $d = 1.0\%$. The *percentage* accuracy should, of course, increase rapidly with increase in the relative lowering measured and although we have as yet made no careful measurements with solutions in which $\frac{p_0 - p}{p_0}$ exceeded 0.02, the results obtained by Berkeley, Hartley and Burton as far as a comparison is justified seem to show in general a degree of concordance of the same order as that given by our apparatus. Their experiments were made at 0° , and the duration of a run was about *three days*.

In the static method for measuring vapor pressure lowering as perfected by Frazer and Lovelace an accuracy of 0.001 mm. is claimed. This would correspond to an accuracy of 0.2% on the value of $\frac{p_0 - p}{p_0}$ for a weight molal solution at 25° and is, therefore greater than that obtained in our experiments with the cane sugar solutions, but of the same order of accuracy as that indicated by the data recorded in Table I. By extending the time of run over several days instead of one, more complete equilibrium could perhaps be obtained with our apparatus but the possible increase in accuracy which might thus be secured has not in most cases seemed worth the additional expenditure of time.

In Frazer and Lovelace's apparatus a minimum of about eight days seems to be required for the attainment of equilibrium and its final measurement, but their results at the end of that period appear to be very accurate, which is more than can be said of any previous attempts to use the static method, and they are to be congratulated upon their success where so many others have failed. We are at present engaged in measuring solutions of mannite at 25° and 35° and as these authors appear to be working with the same solutions we may hope to obtain a direct comparison of results by the two methods for the same solutions.

URBANA, ILLINOIS.

NOTE.

Nichrome Gauze.—Many questions have been asked concerning this gauze, designed in 1911 at Amherst College and since distributed to many of the New England laboratories. It had been the custom to supply

student. near-by paper mills, but on the introduction of water-gas, the brass wire deteriorated rapidly over the Bunsen flame. The nichrome wire was supplied by the Driver Harris Company, of Harrison, New Jersey, to the weavers, Messrs. Howard and Morse, 45 Fulton Street, New York, and proved all that was

desired. In fact, the raw edge of the gauze may be held for a long time in the flame of a blast lamp without any evidence of deterioration of the fine wire; and in the past three years no single gauze has been returned as damaged at the end of a year's service in the laboratories.

The first cost of these gauzes, compared with that of brass wire, is quite high. The standard gauze (5" \times 5") in the first experimental order cost 55 cents each. Later, a larger order was sent amounting to nearly \$400 and the cost of each gauze was reduced to about 25 cents each. As the nichrome seems to last indefinitely, the first cost is gradually eliminated and in the end this gauze becomes cheaper than brass; and at the same time the need of sending a new order each year is eliminated.

The specifications as finally drawn were determined by the following considerations. The British Commission on the Davy Lamp determined that, in order to permit flame to pass, spaces should be at least 0.025" on a side. The following space equivalents are given for various sizes of wire and mesh per inch.

B and S gauze.	30 mesh.	28 mesh.
26	0.0175	0.0198
27	0.0191	0.0215
28	0.0207	0.0231
29	0.0220	0.0244
30	0.0233	0.0257

The choice of No. 30 wire was made because this gives a particularly smooth and flexible gauze; and this was combined with No. 30 mesh as the space equivalent for this combination is nearest to the danger line. With thicker wire or smaller mesh the price advances about 10% for each step. The best gauze is one which is sufficiently open to allow the passage of the maximum heat without allowing flame to pass. The gauze produced proved very satisfactory, allowing—to be exact—a very slight flickering flame about $\frac{1}{8}$ " above the gauze (probably due to the difference in heat conductivity between copper and nichrome) but not enough to damage a glass beaker placed above; and allowing, at the same time, nearly all the heat of the lamp to pass.

The large order of nearly 1600 gauzes was quickly subscribed and no more now remains than sufficient to supply this laboratory; but if a few laboratories care to club together, the same or better terms could doubtless be secured from the weavers, who have kindly assisted us with advice and coöperation in the production of this new article. When one considers the possibility of damage by students' use, the subjection of the red-hot gauze to accidental flooding with concentrated acids or alkalies, the record of not a single damaged gauze in three years is quite remarkable. Satisfaction with this innovation increases with the lapse of time.

AMHERST COLLEGE,

CHLOROPHYLL.

BY RICHARD WILLSTÄTTER.

Received December 23, 1914.

The Method of Investigation.¹

Some years ago, chlorophyll was unknown as a substance in a chemical respect. It was doubtful whether there was one chlorophyll or several pigments related to each other, or a great number of green leaf dyestuffs. The first questions of the analysis were unsolved; it was yet undecided which elements belonged to the chlorophyll molecule. Through the investigations of F. Hoppe-Seyler,² E. Schunck and L. Marchlewski,³ and M. Nencki,⁴ the chief fact found was that the decomposition of chlorophyll leads to pyrrol derivatives which are related to the derivatives from blood pigment.

After some investigations of Hoppe-Seyler⁵ and A. Gautier⁶ (1879) chemists no longer attempted to isolate chlorophyll, for this appeared impossible principally on account of the changeability, the chemical indifference and the easy solubility of the dyestuff diluted, as it was, with so many colorless and yellow accompanying substances. But it was possible, without investigating chlorophyll itself, to deduce the peculiarities of its constitution from the consideration of the derivatives which are obtained by the reactions with acid and alkali.

¹ A more detailed report is given by R. Willstätter and A. Stoll, "Untersuchungen über Chlorophyll," from the Kaiser Wilhelm-Institut für Chemie, Berlin, 1913 (J. Springer).

If alkali hydroxide is allowed to act on chlorophyll, it is changed into salts of chlorophyll, green color. From the neutral chlorophyll, an acid is obtained which forms water-soluble salts. Therefore, without a considerable optical change by the reaction with alkalis, a component which was bound with an acid group is hydrolytically split off. This reaction is the saponification of an ester.

There is another part of the molecule against which the gentle action of acid is directed. The chlorophyll color changes thereby to an olive, at the same time the fluorescence is weakened, a salt-forming group is not formed, showing that saponification is avoided. Therefore, in the splitting with acid, it is possible to preserve and to find in the products of hydrolysis that component which is separated by alkalis, and conversely, the alkali derivatives of the dyestuff must likewise exhibit a characteristic atomic group, which is destroyed with extraordinary ease by acid. According to this guiding idea,¹ it was possible, before chlorophyll itself was known, to determine its characteristics from the analysis of the decomposition products formed by acid and alkali, and indeed so completely, that the analysis at the end gave nothing new when we succeeded in preparing the natural dyestuff pure.

The chlorophyll-green acids, the chlorophyllins, which are formed by alkaline hydrolysis in an alcoholic extract of the leaves, are decomposed very easily, but they can be separated successfully in a fairly pure condition from a mixture with other products of the saponification. They were taken up from their ethereal solution by disodium phosphate and liberated again from it by monosodium phosphate. By analysis, they have been shown to be magnesium compounds.² In them the metal is bound to the nitrogen, the linkage being of a complex nature. The magnesium-containing group is very sensitive towards acids, but it is uncommonly stable against alkalis. It remains intact consequently even in the more far-reaching transformations of the molecule in which the carboxyl groups are split off, one after the other. The presence of magnesium has been proven and the assumed manner of its binding has found confirmation in the results of the continued action of alkalis,³ particularly by the decomposition of the chlorophyllins on heating with concentrated alcoholic alkali to 240°. This yields a series of well-crystallizing, beautifully colored, intensely fluorescent decomposition products, the so-called phyllins with three, two and finally one carboxyl group. All these compounds, of which a number have received names such as glauko- and rhodophyllin, from

their beautiful blue and red color, and of which we have prepared a dozen as homogenous crystals, contain magnesium and at the same time are free acids.

The assumption that a complex is formed by magnesium with the nitrogen atoms has been doubted in the past years, but recently its correctness was proven beyond doubt by the decomposition of the phyllins to the carboxyl-free fundamental substance, the aetiophyllin,¹ the composition of which is expressed by the formula $C_{31}H_{34}N_4Mg$. In consequence of the diminution in the size of the molecule, the ash content has risen to 8% of magnesium oxide. There are only nitrogen-containing groups available, which bind the magnesium with two valencies and fasten it in a complex with secondary valencies. The constitution of the remaining phyllins is analogous, and their oxygen atoms have no part in the binding of the metal complex:

The magnesium content of chlorophyll is constant.² And this has been found, without exception, in land and water plants of the most different classes. For a long time it has been known that magnesia is indispensable as a mineral constituent of plants, but now, for the first time, the definite function of the metal has been established. Inasmuch as it is not a case of catalytic influence, such as is ascribed to iron for chlorophyll formation, but a stoichiometric participation of the magnesium in the building up of chlorophyll, the attention of the agricultural chemists should be directed to the question whether magnesia is provided by nature in sufficiency for the useful plants. The effect of an addition of magnesium salt on the chlorophyll formation and growth with different kinds of cultures was investigated a short time ago by E. Mameli³ in the Botanical Institute at Pavia and a favorable influence of added magnesium was found.

All the phyllins lose magnesium by the action of mineral acids, as well as by acetic acid; the carboxylic acids of the phyllin series pass, thereby, into polybasic or monobasic amino acids which display characteristic basic properties besides the acid ones. They form a natural group with the phylloporphyrin discovered by F. Hoppe-Seyler,⁴ later investigated,

⁴ *Z. physiol. Chem.*, 4, 193 (1880).

but not obtained in a pure condition, by E. Schunck.¹ Therefore, they are named porphyrins and that prefix is added which belongs to the corresponding phyllin. From the oxygen-free aetiophyllin, the simplest porphyrin, aetiophorphyrin, of the formula $C_{31}H_{38}N_4$ is formed.

Analogous to the behavior of the phyllins towards acid is the action of acids on the solutions of chlorophyll itself. For the investigation of this reaction, the observation was fundamental that, by gentle decomposition with oxalic acid, a chlorophyll derivative, the so-called phaeophytin which is not readily soluble in alcohol and free from colorless and yellow accompanying substances, is precipitated almost quantitatively from an alcoholic extract of the leaves. It no longer contains magnesium, and the splitting off of the metal is the only change which has occurred, if the preparation of the plant material, the extraction, and the treatment with acid is made with all the precautions which are suggested by the experience of this work.

The phaeophytin recalls to mind the substances which F. Hoppe-Seyler² in 1879 and at the same time A. Gautier³ obtained as products of the unintentional decomposition of chlorophyll by the plant acids, contained in the extracts. The old preparations,⁴ however, were not free from accompanying substances and not intact in the easily changeable atomic groups of the dyestuff molecule. Hoppe-Seyler found in such a substance, the chlorophyllan, a phosphorus content of 1.4% and was thereby led to the supposition that chlorophyll might belong to the lecithins. The hypothesis, cautiously expressed by Hoppe-Seyler, is ardently upheld by J. Stoklasa⁵ up to the present day, who states to have found phosphorus and potassium in chlorophyll, and indeed more phosphorus than in lecithin. This experience cannot be corroborated.⁶ The long and uncertain way by which chlorophyllan used to be obtained is now replaced by a method which permits us to separate the chlorophyll of any origin as a pure derivative. It can now be obtained on a kilogram scale by the ordinary means of the laboratory; the meal of dried common nettle leaves is a suitable starting material (yield 4 to 6 g. phaeophytin from 1 kg.).

The phaeophytin is a wax-like substance without acid properties and of a weak basic nature. As regards the color of its solutions, it is quite different from chlorophyll, but the similarity of this decomposition product to chlorophyll appears as soon as a metal is introduced into the molecule,

in which it becomes bound as a complex.¹ Many metals enter very easily, for example, copper and zinc by the action of their acetate salts on the alcoholic solution of phaeophytin. The complex formation is a phenomenon so evident that the smallest traces of certain metals can be shown by the aid of chlorophyll derivatives. It was much more difficult to reintroduce the magnesium on account of the sensitiveness of the magnesium complex to acids. This has been attained² finally by the action of the Grignard solutions, for example, of magnesium methyl iodide on phaeophytin or on porphyrins. Another method, namely, the action of magnesium oxide and alkali in the heat, is not applicable for the reformation of chlorophyll on account of its instability towards alkali, but is very suitable for the formation of the phyllins from the porphyrins. In the same manner, iron can be introduced into the porphyrins by heating with methyl alcoholic potassium hydroxide and iron oxide.

Phaeophytin³ behaves like a wax upon saponification with alkalis and produces, besides high molecular nitrogen-containing acids with 34 atoms of carbon, a nitrogen-free alcohol with twenty carbon atoms. It has been isolated and called phytol. It has the formula $C_{20}H_{39}OH$ and is an unsaturated primary alcohol with an open chain of carbon atoms. Investigations⁴ concerning its decomposition have made it probable that its carbon skeleton has many side-chains and that it contains many methyl groups. For its structure, the following constitutional formula, which is hypothetical in its details, may serve provisionally:

It is probable that relations exist between isoprene, the well-known building stone of the terpenes and caoutchouc, and this alcoholic component of chlorophyll.

Consequently the chlorophyll derivative, formed by acid, has yielded the information which was sought concerning the chief transformation which the alkalis produce upon the molecule of chlorophyll; they saponify the phytol ester group. The action, however, is not limited to this group; for the phaeophytin, and as a result the chlorophyll, contains further a $COOCH_3$ group which also is decomposed by the hydrolysis.

Phytol is of general occurrence⁵ in nature, amounting to one-third of

the weight of chlorophyll, and the phytol occurs constantly as a component of chlorophyll. This knowledge was obtained in an indirect manner by working up different plants. In the beginning, the phaeophytin preparations of different origin showed considerable fluctuations. The phytol content never exceeded 33% but not infrequently remained below that figure and in many cases sank to zero. Now it has been found that just those plants containing a chlorophyll poor in phytol proved to be an excellent material for the isolation of chlorophyll in a peculiar form of beautiful crystals.¹ These crystals were the same which the Russian botanist J. Borodin² discovered under the microscope in 1881. Borodin observed the formation of crystals under certain conditions, namely, when drying alcohol-moistened sections of leaves. He left the question open, however, whether these crystals originated from chlorophyll or from transformed chlorophyll. N. A. Monteverde³ continued the investigation and isolated such crystals in a small quantity in order to characterize them spectroscopically. But the substance had not been analyzed and chemically investigated. In the monographs concerning chlorophyll, Borodin's research was not mentioned. The discovery, therefore, remained useless until it was made a second time in the chemical laboratory. In 1907, I obtained, together with Benz, the so-called crystallized chlorophyll on a large scale, but at a time when the analysis of chlorophyll had been already completed by indirect methods. The production of crystallized chlorophyll on a preparative scale was of special value for investigations, until it became possible to separate the natural dyestuff itself in a pure condition.

The formation of the crystallized compound and the corresponding deficiency of phytol could be explained only by the observation⁴ that by rapid extraction of many leaves the phytol content is normal. But by slow extraction, when the extract remains in contact with the meal of dried leaves for some time, it is too low. According to Willstätter and Stoll,⁵ the chlorophyll in the green plant parts is accompanied by an enzyme, the chlorophyllase, belonging to the esterases. This is not inactive in alcoholic media, as is generally assumed for enzymes, but it causes the displacement of the phytol by the alcohol applied as a solvent and thereby effects alcoholysis of the chlorophyll. The enzyme occurs pretty generally; for example, it is contained in large quantity in *Galeopsis* and *Heracleum*, but its quantity appears to fluctuate within wide limits. After the dynamics of this enzyme reaction had been sufficiently studied,

extensive application of the action of chlorophyllase was made for preparative purposes. There is no longer anything accidental about the preparation of crystallized chlorophyll. From fresh, as well as from dried leaves, almost the total chlorophyll can be separated in the form of the ethyl or methyl compound (ethyl or methyl chlorophyllide) or through hydrolysis in the form of the corresponding free carboxylic acid, the chlorophyllide.¹ The reversal of the hydrolysis, the partial synthesis² of chlorophyll from the two components, has also been carried out, namely, from chlorophyllide with the alcohol phytol by esterification under the catalytic influence of chlorophyllase. The usual methods of ester formation could not be applied in this case on account of the sensitiveness of chlorophyll.

Inasmuch as the phaeophytin is the most suitable form of chlorophyll for investigation as well as for the comparison of the leaf green from different plants, the characterization of chlorophyll, apart from the determination of magnesium and phytol, requires above all the knowledge of the nitrogen-containing acids which result, besides the phytol, upon saponification of phaeophytin. Although this is a pure chlorophyll substance, it is not a homogeneous compound; its acid component contains substances which differ in basic properties and color.³ In the beginning, the investigation led to a great number of such decomposition products which form two groups; the one, phytochlorins, olive-green in indifferent solution, the other, phytorhodins, beautifully red. On account of their great number, the single compounds are designated with group names and letters added to them.

We would have scarcely succeeded in throwing light on the mixture of complicated composition which is met by the first transformations of chlorophyll if the basic nature of the decomposition products, in their unprecedented differentiation, had not placed in our hands a never-failing method⁴ for the determination and separation of chlorophyll derivatives. This method (Willstätter and Mieg) depends on the different distribution of these dyestuffs between ether and hydrochloric acid. The proportion in which these bases are distributed between ether and dilute acids varies in a most unusual manner with the acid concentration. The concentration of the acid, which under ordinary conditions extracts a large quantity of the substance from ether, is so important for preparative purposes that particular weight must be attached to it. We call "the

The decomposition products of phaeophytin, occurring in mixtures, were therefore separated by fractionation of their ethereal solution with hydrochloric acid of varying concentration. But the appearance of complicated mixtures was only a result of certain transformations, which the chlorophyll, being very changeable in alcoholic solution, underwent under the experimental conditions, as, for example, too slow extraction or too slow precipitation with acid. The preliminary treatment of the plant material and particularly its extraction and the treatment of the extract with acid had to be improved and to be made more uniform. By looking for the causes of the changes appearing in the solutions and by learning to avoid them, the differences between our preparations have become less frequent and more insignificant and we have finally succeeded in obtaining two, and only two, well-crystallizing and characteristic decomposition products from phaeophytin:¹ Phytochlorin *e* of the composition $C_{34}H_{34}O_5N_4$ and phytorhodin *g* of the composition $C_{34}H_{34}O_7N_4$.

Phytochlorin *e* is a tricarboxylic acid with two free carboxyl groups and one bound as a lactam. Phytorhodin *g* is a tetracarboxylic acid; of its carboxyl groups only two or three are found in a free condition.

The common appearance of a green and red decomposition product

¹ R. Willstätter and M. Isler, *Ann.*, 380, 154 (1911); R. Willstätter and M. Utzinger, *Ibid.*, 382, 129 (1911); R. Willstätter and M. Isler, *Ibid.*, 390, 269 (1912).

by the subsequent hydrolysis of chlorophyll with acid and alkali opened up an important question.¹ Is it caused by the decomposition of a large molecule into two fragments? As an argument against this we find the molecular weight of phaeophytin to be of similar magnitude to that of phytochlorin and phytorhodin. Then again, it might be conceivable that one of the decomposition products represents an earlier, the other a subsequent step of decomposition. But phytochlorin and phytorhodin cannot be converted into each other, and they are formed in quite definite weight proportions. It followed, therefore, from the formation of phytochlorin *e* and phytorhodin *g* that phaeophytin, and consequently chlorophyll, is a mixture of two components from which the one furnishes phytochlorin *e* by decomposition, the other phytorhodin *g*. On this basis, we have succeeded in obtaining the separation of the components from the mixture by physical and chemical means.

One method² which can be applied with chlorophyll solutions, with crystallized chlorophyll and with phaeophytin, consists in the rearrangement of the given proportion by unequal distribution of the dyestuff between several solvents, immiscible with one another; for example, water containing methyl alcohol with petroleum ether or, in the case of the difficultly soluble phytol-free compounds, methyl alcohol with ether-petroleum ether. This rearrangement of the relation of the components can be repeated and so utilized by numerous repetitions of the operations that, finally, the two components of the magnesium-bearing free dyestuffs are in pure condition.

The other method,³ which of course is only applicable with magnesium-free compounds, consists in the fractionating with hydrochloric acid, according to the method of Willstätter and Mieg. The phaeophytin is so weak a base and so sensitive in its phytol-ester group toward hydrolytic agents, that this separation was not obvious and offered particular obstacles. It served its purpose, nevertheless, and confirmed the results of the first method of separation.

These results have corroborated a view which G. G. Stokes⁴ expressed as early as 1864, unfortunately in only a few short words. Stokes recognized chlorophyll spectroscopically as a mixture and he endeavored to separate it by distribution between alcohol and carbon disulfide, a method subsequently rediscovered and developed by H. C. Sorby⁵ and G. Kraus,⁶

⁶ G. Kraus, *Zur Kenntnis der Chlorophyllfarbstoffe und ihrer Verwandten*, Stuttgart, 1872.

and much applied since then, particularly to show that yellow pigments accompany the green dyestuff. Recently, the botanist M. Tswett¹ in Warsaw has confirmed in a new, original way the view of Stokes, namely, by a separation of the natural pigment on an analytical scale by means of fractional adsorption from its solutions. It was impossible up to the present time, however, to find whether the dyestuff had changed or not by the extraction and during the following manipulations. Such changes occur easily and explain considerable errors which can be found in the work of Stokes, Sorby and Tswett. According to Stokes,² Sorby³ and Tswett,⁴ a third chlorophyll component occurs as a pigment of *Phaeophyceae*. An investigation⁵ of the pigments of seaweeds, carried out recently, has led to the result that the chlorophyll of this algae is identical with that of land plants, with the exception that component *b* is reduced in quantity. The supposed third chlorophyll dyestuff was in fact a decomposition product of chlorophyll.

Whether the chlorophyll molecule remains intact in its details must be tested by decomposition to the typical splitting products (phytochlorin *e* and phytorhodin *g*). This characterization of the constituents of the leaf-green was the condition for the final isolation of the chlorophyll in an unchanged and pure state in form of a mixture or as individual components.

Isolation of Chlorophyll and Separation into Its Components.

The isolation of chlorophyll (Willstätter and Hug, 1911) was controlled by the colorimetric determination of the degree of purity of its solutions and depended on systematic increase of the purity in the course of a "un-mixing process," in which the distribution of the substances, contained in the extracts, between several solvents is applied in a particular manner, in order to separate the yellow and, still more, the colorless substances accompanying the chlorophyll. Solutions of about 70% chlorophyll result by the un-mixing method from the extracts which, in consequence of the great quantity of accompanying colorless substances, contain only 8-16% chlorophyll. Then, finally, an unexpected observation aided in the solution of the problem. When the chlorophyll has reached a certain degree of purity, it is still easily soluble in alcohol containing petroleum ether but, surprisingly, no longer soluble in pure petroleum ether. If the ethyl or methyl alcohol is removed by washing, the chlorophyll is precipitated and it can be purified by further precipitations from ether by petroleum

ether. In the beginning, this procedure¹ was laborious and the yield was small. In newer researches with A. Stoll,² I have perfected the procedure by variations in the methods of extraction and separation.

The materials for our work on a large scale are mostly dried and pulverized leaves. It has been shown that a considerable water content of the solvent essentially facilitates and accelerates the extraction of the

Fig. 1.

total leaf dyestuff. The pigments in the chloroplasts, even after drying, are found in a colloidal condition and are difficultly soluble. They are coagulated by a solvent which dissolves salts out of the material and are

¹ R. Willstätter and E. Hug, *Ann.*, 380, 177 (1911).

² R. Willstätter and A. Stoll, "Untersuchungen über Chlorophyll," Chaps. III and VI.

therefore made more easily soluble. Besides, the quantity of the accompanying substances going into solution is increased and it is no longer the solvent itself but a mixture with the accompanying substances which becomes the particular means of extraction for the green of the leaf and, indeed, one so excellent, that the dyestuffs are quickly, easily and almost quantitatively extracted by it. It appears as if actually the whole chloroplast substance was carried off by the solvent with suitable water content.

The best solvents are 85 to 90% alcohol and especially 80 to 85% acetone; the following figures show the influence of the water percentage on the chlorophyll content of the extract.

At the present time we can isolate pure chlorophyll in a few hours without much trouble from a few kilograms of dried leaves with a yield of about 80% of the quantity, that is, about 6.5 g. from a kg. of dried leaves. The procedure can also be carried out with fresh leaves, and likewise, as in the whole course of the work, no difference between the freshly plucked and the dried leaves resulted in the production of the chlorophyll preparations and in their properties. In a lecture hour, a quarter of a gram of pure chlorophyll can be isolated from a quarter of a kilogram of fresh common nettles. The leaf dyestuff can be isolated, at present, as easily as any kind of a plant constituent, as an alkaloid or a sugar.

With our methods of separation the two components are divided in an unequal manner between methyl alcohol and petroleum ether. By systematic fractionating, the rearrangement of the proportion of the components to each other is continued so far that finally the two components¹ result quite homogeneous from the mixture. The one component, chlorophyll *a*, is bluish green, the second, chlorophyll *b*, yellowish green. Their composition, in spite of their optical difference,² is very similar. The distinction is due to a different degree of oxidation. With the chlorophyll itself, we find confirmed what the formulae of phytochlorin *e* and phytorhodin *g* predicted, namely, that the compounds of Series *b* are derived from the compounds *a*, and probably in such a manner that two atoms of hydrogen are replaced by an atom of oxygen. This substitution, corresponding to the formulas: chlorophyll *a* $C_{55}H_{72}O_6N_4Mg$, *i. e.*, $[C_{32}H_{40}ON_4Mg](CO_2CH_3)(CO_2C_{20}H_{39})$ and chlorophyll *b* $C_{55}H_{70}O_6N_4Mg$, *i. e.*, $[C_{32}H_{38}O_2N_4Mg](CO_2CH_3)(CO_2C_{20}H_{39})$ means a difference of a molecule of oxygen.

Such a result does not appear certain, considering the size of the chlorophyll molecule. The difference, as far as the analyses show, could be CO_2

¹ R. Willstätter and M. Isler, *Ann.*, **390**, 269, 327 (1912); R. Willstätter and A. Stoll, "Untersuchungen über Chlorophyll," Chap. VI.

² "Ueber die Absorptionsspektren der Komponenten und ersten Derivate des Chlorophylls," R. Willstätter, A. Stoll and M. Utzinger, *Ann.*, **385**, 156 (1911); R. Willstätter and A. Stoll, "Untersuchungen über Chlorophyll," Chap. XXV.

instead of O_2 and that would be important for the explanation of the chemical function of chlorophyll. The assumed relation between the two components, however, is made more likely by the behavior of the derivatives of chlorophyll *b* toward the Grignard reagent,¹ by which they are converted into components of Series *a*, and further through the course of the decomposition which, in the *b* series, leads to the same aetiophyllin and aetioporphylin.²

The Carotinoids.

In the preparation of the leaf-green, the separation from the yellow accompanying substances, which are extraordinarily widely spread in the plants and are associated with chlorophyll in the chloroplasts, was an important problem. The common occurrence of the yellow dyestuffs with the green, points to a significant physiological role of these carotinoids. In every green leaf, there occur two well-crystallizing nitrogen-free pigments of many common properties, but differing in their behavior towards solvents. One of these, as A. Arnaud³ has made probable, is identical with the carotin of carrots which has been known a long time. The analyses of Willstätter and Mieg⁴ have shown that it is an unsaturated hydrocarbon of the formula $C_{40}H_{56}$. Its companion, xanthophyll,⁵ was yet unknown in substance, in spite of the fact that it predominates in regard to quantity in the leaves. According to its composition, $C_{40}H_{56}O_2$, and its properties, it is to be considered as an oxide of carotin. The hydrocarbon is considerably soluble in petroleum ether, the oxygen compound, on the other hand, only in alcohol. A great affinity for oxygen, which they greedily absorb, particularly in their solutions, is peculiar to both the yellow pigments.

A third carotinoid, the fucoxanthin, is found in the olive-colored seaweeds and it has been recently isolated in pure crystals;⁶ its composition is $C_{40}H_{54}O_6$. It is similar to carotin and xanthophyll in a chemical respect, but distinguished from them by the considerable basic property of its oxygen atoms, bound in the manner of an ether. It forms a characteristic blue hydrochloride which is to be considered as an oxonium salt. The constitution of these yellow pigments has not been explained hitherto, as their decomposition produced only amorphous substances.

Comparative Investigation of the Leaf Pigments.

The description and analysis of chlorophyll and its yellow companions furnish the conditions for the determination of the quantitative relation

between all the components of the leaf dyestuff and for the comparison of the leaf-green in the most different kinds of plants. The material for the comparison was obtained from the most characteristic chlorophyll, that of the cryptogamia and phanerogamia. Our method consisted in the examination of phaeophytin, which was separated by quick extraction of the leaves and quick precipitation with acid, by its phytol content as well as by its basic decomposition products, phytochlorin *e* and phytorhodin *g*, and for completion the decomposition of the chlorophyll alkali salts to the crystallizing rhodophyllin, in which the ash amounts to 7% of magnesium oxide. The result¹ is the identity of chlorophyll in all plants investigated. We find only one single leaf-green consisting of the two components, *a* and *b*, of chlorophyll. We also observe a great regularity in the quantitative relation between these; chlorophyll *a* predominates, at the rate of almost three molecules to one molecule of chlorophyll *b*. Only the seaweeds (*Phaeophyceae*) form an exception² to this quantitative relation, containing besides the chlorophyll *a*, only a diminishingly small quantity of component *b*.

The molecular proportion of the green to the yellow pigments is also approximately constant, that is 3 : 1, and the relation of carotin to xanthophyll, with insignificant fluctuations in light leaves, stands 0.6 : 1.

An example might illustrate the results: In 1 kg. of dried elder leaves (corresponding to 4 kg. of fresh leaves) are contained: 8.48 g. chlorophyll, that is, 6.22 g. chlorophyll *a*; 2.26 g. chlorophyll *b*; 1.48 g. carotinoids, that is, 0.55 g. carotin; 0.93 g. xanthophyll. These quantities correspond to the following molecular proportions: For 1 molecule chlorophyll (*a* + *b*) there occurs 0.35 molecule of carotinoids. For 1 molecule chlorophyll *a* there occurs 0.36 molecule of chlorophyll *b*.

Questions of Constitution.

If we consider the decomposition of the two chlorophyll components to aetiophyllin and aetioporphyrin, we see many intermediate products on the way to the mother substance, namely, the magnesium containing acids, the green, blue and red phyllins which are formed by the saponification of chlorophyll and by further heating with alkali. From them are derived the magnesium-free compounds, among which, the phaeophytins, phytochlorin *e* and phytorhodin *g*, and the porphyrins are important.

Phaeophytin is formed from chlorophyll *a* by the loss of magnesium and yields phytochlorin *e* on treatment with alkali. The latter is also formed when alkali and then acid acts on chlorophyll.

¹ R. Willstätter and M. Isler, *Ann.*, **380**, 154 (1911); **390**, 269 (1912); R. Willstätter and A. Stoll, "Untersuchungen über Chlorophyll," Chaps. IV and V.

² R. Willstätter and H. J. Page, *Ann.*, **404**, 237 (1914).

The relation between chlorophyll and the chlorophyllin-salts is not a simple one. Two alkali salts, obtained in a homogeneous form, result from each chlorophyll component, according to the conditions of the hydrolysis. One fluoresces, like chlorophyll itself, while the other is lacking fluorescence (chlorophyllin and isochlorophyllin¹). The reaction consists not only in the saponification of two ester groups but, first and foremost, in a specific transformation which is recognized by the appearance of the so-called brown phase. Only a correct explanation of this brown phase² can give the key for the theory of the first steps of decomposition and of the changes which chlorophyll so easily and spontaneously undergoes in its solutions. Let us picture in our minds that, by the action of alkalies on chlorophyll and chlorophyllids, the green color at first changes to an intense brown, to a yellowish brown with the component *a*, to a red with *b*, and then in some minutes, the original chlorophyll color returns in the alkaline medium. The reaction has the appearance of a complete decomposition and a new formation of chlorophyll. Of course, it must be understood that a group, essentially responsible for the chromophoric complex, is changed by hydrolysis and that a new similar one is formed in its place.

We attempt to explain this behavior of chlorophyll as a "re-lactamization," as the opening of an existing lactam ring and the closing of a new ring, similar, but nevertheless stable in alkali. The formation of a new lactam ring can result in several ways: the different series of chlorophyllins and the hardly avoidable occurrence of the weak basic phytochlorins and phytorhodins are explained by it.

The original group may be marked:

It can so relactamize that, for example, the carboxyl γ enters into combination with another nitrogen group, called δ , or the relactamization can re-

¹ R. Willstätter and M. Utzinger, *Ann.*, **382**, 129, 157 (1911); R. Willstätter, M. Fischer and L. Forsén, *Ibid.*, **400**, 147 (1913); R. Willstätter and A. Stoll, "Untersuchungen über Chlorophyll," Chap. XVIII.

² R. Willstätter and M. Utzinger, *Ann.*, **382**, 128, 135, 139 (1911); R. Willstätter and A. Stoll, *Ibid.*, **387**, 317, 326 (1911).

sult in such a manner that another carboxyl, namely, α , unites, for example, with the γ amino group. This reaction takes place in a different manner when carried out in the cold or with very concentrated alkali at a higher temperature. Chlorophyll also, by standing in alcoholic solution, changes for the same reason. This change, which can be induced by traces of an acid, has been called allomerization.¹

Since the ring-groups, newly formed by the first attack of the alkali on chlorophyll, are more stable than the original ones, the different course of the relaxtamization causes remaining differences in the products of further decomposition. Corresponding series of simpler composed phyllins and porphyrins therefore originate from the two fundamental derivatives of each chlorophyll component, the chlorophyllin and the isochlorophyllin. There are altogether four series of acids² produced by the alkaline decomposition which lead finally to a single end-product.

From isochlorophyllin *a* arise the dicarboxylic acid cyanophyllin, blue in solution; the dicarboxylic acid erythrophyllin, red in solution; the monocarboxylic acid phyllophyllin, blue, tinged red in solution.

From chlorophyllin *a* result the dicarboxylic acid glaukophyllin, blue in solution; the dicarboxylic acid rhodophyllin, bluish red in solution; the monocarboxylic acid pyrrophyllin, blue, tinged red in solution.

Willstätter and Fischer³ have recently succeeded in splitting off the last carboxyl group from the phyllins and porphyrins by heating them in very small quantities with soda lime. As a result the same aetiophyllin ($\text{C}_{31}\text{H}_{34}\text{N}_4\text{Mg}$) and aetioporphyrin ($\text{C}_{31}\text{H}_{36}\text{N}_4$) have been obtained from

¹ R. Willstätter and A. Stoll, *Ann.*, 387, 357 (1911).

² R. Willstätter, M. Fischer and L. Forsén, *Ibid.*, 400, 147 (1913).

³ *Ann.*, 400, 182 (1913).

the derivatives of chlorophyll *a* and *b*. These nuclei substances are well-crystallizing compounds, which fit into the group picture of the phyllins and the porphyrins previously investigated.

In order to simplify the consideration of the structure of chlorophyll, I would like to restrict myself to a discussion of the formula of aetioporphyrin. It must take into account the results of the oxidation and the reduction of chlorophyll derivatives. By oxidation,¹ phylloporphyrin furnishes compounds which are well known from the investigation of W. Küster² on the decomposition of Haemin. I refer to methyl-ethyl-maleic-imid,

of which more than one molecule is obtained and further to haematic acid, which is produced in molecular quantity:

The reduction³ of the porphyrins yields haemopyrrol, which was chiefly known as a reduction product of the blood dyestuff. M. Nencki and L. Marchlewski⁴ have been the first to obtain it from a chlorophyll derivative. Together with Asahina, I have shown that it has a surprisingly complicated composition, being a mixture of three components, at least. We have isolated from it a tetra-substituted pyrrol, the phyllopyrrol. Hans Fischer and Bartholomaeus,⁵ further O. Piloty⁶ and L. Knorr,⁷ have contributed to the explanation of different haemopyrrol components of which the following are now known exactly:

¹ R. Willstätter and Y. Asahina, *Ann.*, 373, 227 (1910).

² *Z. physiol. Chem.*, 28, 1 (1899); 29, 185 (1900); 44, 391 (1905); 54, 501 (1908); 61, 164 (1909); *Ann.*, 315, 174 (1900).

⁴ *Ber.*, 34, 1687 (1901).

⁵ *Ibid.*, 44, 3313 (1911); 45, 1979 (1902); 45, 466 (1912); *Z. physiol. Chem.*, 77, 185 (1912); 80, 6 (1912).

⁶ *Ann.*, 366, 237 (1909); 377, 314 (1910); O. Piloty and E. Quitmann, *Ber.*, 42, 4693 (1909); O. Piloty and J. Stock, *Ann.*, 392, 215 (1912) and *Ber.*, 46, 1008; O. Piloty and K. Wilke, *Ibid.*, 46, 1597 (1913).

⁷ L. Knorr and K. Hess, *Ibid.*, 44, 2758 (1911); 45, 2626 (1912).

The aetioporphyrin therefore is composed of four pyrrol nuclei. The number of its hydrogen atoms is strikingly low, which implies that the pyrrols must be so united and substituted by double bonds or further closing of rings that eight atoms of hydrogens less are required than if there were simple bonds. If the ethyl groups, necessary for the explanation of the oxidation products, are taken into consideration, it does not appear possible to formulate the aetioporphyrin without the assumption of a carbon ring. Several suggestions are met with in the literature on haemin by W. Küster¹ and O. Piloty² as to the combination of the pyrrol nuclei, but the question has not been solved by them. I consider the following formula probable to represent a simple union to a dyestuff of four pyrrol nuclei, of which two are salt-forming and two complex-forming:

If we substitute this parent substance, in respect of the oxidation products, with three methyl and three ethyl groups and, in respect of the reduction products, with at least another methyl group, there remains finally only so much hydrogen left for the last three carbon atoms that either two double bonds or two carbon rings or one of both must be assumed. If the assumption of a cyclopentane or hexane ring, corresponding to the course of the reduction, is avoided, we arrive, with some probability, at the following formulae for aetioporphyrin and aetiophyllin:

Aetioporphyrin, $C_{31}H_{38}N_4$

¹ *Z. physiol. Chem.*, 82, 463 (1912).

² *Ann.*, 388, 313 (1912); 392, 215 (1912).

Aetiophyllin, $C_{31}H_{34}N_4Mg$.

Several details of this formula, as the position of two methyl groups, are arbitrary. The cyclobutene ring could also be attached to the pyrrol in the β, β -position.

The question of the constitution seems to be the more important, as I have succeeded together with M. Fischer,¹ a short time ago, in breaking down the blood dyestuff to aetioporphyrin. There has been obtained, for the first time, a transformation product, from haemin and chlorophyll, whose molecule still stands in close relation to the dyestuff itself. Up to this time, only the decomposition products of haemin and chlorophyll, simple pyrrol derivatives, produced by oxidation and reduction, have been identical. The porphyrins from both pigments exhibited great similarity, which Hoppe-Seyler as well as Schunck and Marchlewski recognized, but nevertheless show considerable differences, for example, in their basic properties.

The porphyrins result from haemin through an entirely different reaction than from chlorophyll, and indeed not simply by the withdrawing of the metal. Haematoporphyrin, the product of the action of hydrobromic acid on haemin, is a dihydroxy acid. It has been possible to reduce haematoporphyrin to a new porphyrin, which I have called haemoporphyrin, by heating with methyl alcoholic potassium hydroxide and pyridine. This product differs in its composition from haematoporphyrin by minus two hydroxyl groups. Like the rhodoporphyrin, with which it is isomeric, it can be decarboxylated by heating with soda lime. From the composition $C_{31}H_{36}N_4$ of the aetioporphyrin so obtained, it follows that haemoporphyrin corresponds to the formula $C_{33}H_{36}O_4N_4$, and consequently haemin does not correspond to the generally adopted formula $C_{34}H_{32}O_4N_4 \cdot FeCl$ but to the formula $C_{33}H_{32}O_4N_4 \cdot FeCl$. While the aetioporphyrin of the formula $C_{31}H_{36}N_4$ already appears strikingly poor in hydrogen, haemin, $C_{33}H_{32}O_4N_4 \cdot FeCl$, is derived from a parent substance, $C_{31}H_{34}N_4$, still poorer

¹ *Z. physiol. Chem.*, **87**, 423 (1913).

by two hydrogen atoms, which renders it necessary to assume double bonds as well as peculiar carbon rings. Upon the basis of a new research¹ on the reactions leading from haemin to haematoporphyrin, I have tried to develop a constitutional formula of haemin explaining the behavior upon oxidation and reduction and also the porphyrin formation. In many details it has not been proved but, as I hope, it may serve to guide further investigation.

Although chlorophyll and haemin have been traced back to the same aetioporphyrin, which can be called a parent substance, we do not draw the conclusion of a near constitutional relationship between chlorophyll and haemin from the investigations of the decomposition. In one, there is magnesium, in the other iron, in one ester formation with phytol, in the other a combination with globin. In addition to such differences, corresponding to the function of a different kind, there are further significant dissimilarities in the real nucleus of the dyestuff which have disappeared only by far-reaching decomposition. On the way from haemin to aetioporphyrin there are two transformations, which essentially change the construction of the molecule, namely, the transition from haemin to haematoporphyrin and from this to haemoporphyrin, which is isomeric with the porphyrins of chlorophyll. Between chlorophyll and aetiophyllin and even between chlorophyll and the first dibasic porphyrins, as cyanoporphyrin or erythroporphyrin, there are two steps, essentially transforming the molecule. They cannot be compared with the reactions of haemin.

Future investigations on the constitution of chlorophyll will still find important problems. The relations between the two chlorophyll components and the transformations which lead from chlorophyll to the chlorophyllins and from the chlorophyllins to the dibasic phyllins, are to be explained and the structure of aetioporphyrin is still to be investigated in important details. Of still greater importance are the questions which

¹ R. Willstätter and M. Fischer, *Z. physiol. Chem.*, **87**, 423 (1913).

plant physiology asks and their solution will perhaps be aided by the isolation and the study of the components of the leaf dyestuff. These questions refer to the possibility of a chemical function of chlorophyll and to its nature.

BERLIN-DAHLEM, GERMANY.

**ON THE ESTERS, AS WELL AS THE MONOMOLECULAR β - AND γ -LACTONES, OF *d*-MANNONIC AND *d*-GLUCONIC ACIDS;
ON ORTHO-BIS-*d*-GALACTONIC ACID, *d*-GALACTONIC
 γ -LACTONE AND ITS MONO-HYDRATE.**

BY OSCAR F. HEDENBURG.

Received December 5, 1914.

A very condensed description of the properties and methods of preparation of the various compounds named in the above title has very recently been published by Nef,¹ who also discusses in detail the significance of the discovery of α -, β - and γ -lactones of the polyhydroxy acids, $C_nH_{2n}O_{n+1}$, in coming to a decision on the question of the constitution of the α - and β -modifications of aldose and ketose sugars, as well as of the α - and β -glucosides. He has reached the conclusion that the various crystalline forms of the simple sugars,² including also malt and milk sugars, are to be represented either by the free ketose or aldose structure,

$$CH_2OH(CHOH)_x - \overset{\overset{O}{\parallel}}{C} - CH_2OH \text{ and } CH_2OH(CHOH)_{x+1} - CHO \text{ (or}$$

at times by a corresponding ketose or aldose monohydrate structure, analogous to chloral hydrate, etc.), or, by a monomolecular α -lactone formula,

Generally only one of these two, or, in the case of the ketoses, three forms,

¹ *Ann.*, **403**, 273-9, 306-331 (1914).

² In many cases the hydrazones, oximes, anilides and osazones of aldose and ketose sugars are known to show multarotation; this is unquestionably due to the existence of two or more analogous structural isomers, which have frequently been isolated, but have hitherto almost invariably been regarded as space isomers.

can be obtained pure by crystallization; the other modification, when isolated by Tanret's method for example, usually consists only of mixed crystals of which theoretically a limitless number are possible. Thus α -*d*-glucose, $[\alpha]_D^{20} = +104^\circ$, m. p. 156° , must be represented by the α -lactone formula, whereas Tanret's β -*d*-glucose, $[\alpha]_D^{20} = +22.5^\circ$, can not conceivably represent the pure aldehyde modification of *d*-glucose whose specific rotation must be slightly laevo, but consists of a mixture of about 80% of aldehyde sugar, contaminated with 20% of α -lactone. Crystallized *d*-mannose, $[\alpha]_D^{20} = -2^\circ$, on the other hand, corresponds to the free aldehyde form, whereas the α -lactone modification, which exists to the extent of about 20% in an aqueous solution of *d*-mannose after 24 hrs. standing, $[\alpha]_D^{20} = +16^\circ$, and which must undoubtedly possess $[\alpha]_D^{20} =$ over $+100^\circ$, has not as yet been isolated in a pure condition. Crystallized *d*-fructose finally, whose melting point invariably ranges from 105° – 115° , probably consists of a mixture of the two α -lactones, 2,3- and 1,2- α -*d*-fructose, etc., etc.

The so-called α - and β -glucosides, on the other hand, possess respectively, γ - and β -lactone structure, *e. g.*, α -methyl *d*-glucoside,

It will be seen at once, therefore, that only the α -glucosides retain the γ -lactone structure hitherto ascribed in all the text books also to the α - and β -sugar modifications, as well as to the β -glucosides; they should therefore be renamed γ -glucosides in accord with their structure, especially as α -glucosides of the formula,

representatives of this class have not yet actually been isolated.

The problem assigned to me by Dr. Nef, therefore, was to confirm and extend his observations on the preparation and properties of the various derivatives of *d*-mannonic, *d*-gluconic and *d*-galactonic acids named above, as well as to make a thorough search for other derivatives possibly overlooked by him and especially to analyse, titrate and to determine the molecular weights and physical constants of the new compounds obtained. Many of my results are to be found in Nef's paper in *Liebig's Annalen*; they are, however, given here in greater detail and many new observations are included.

Experimental Part.

I. On Ethyl *d*-Mannonate, and on *d*-Mannonic β - and γ -Lactones.

***d*-Mannonic β -Lactone.**—This is the normal and practically the only lactone formed from free *d*-mannonic acid, $[\alpha]_D^{20} = -1^\circ$,¹ at ordinary temperatures; γ -lactone formation also takes place, although very slowly at lower temperatures, but far more rapidly as the temperature is raised. In order, therefore, to obtain the maximum yield of β -lactone an aqueous solution of *d*-mannonic acid should not be heated higher, nor longer, than absolutely necessary. Such a solution² is best prepared by adding the calculated amount of crystallized oxalic acid in water to an aqueous solution of calcium *d*-mannonate heated to 50° . The mixture is thereupon cooled within five minutes to about 20° and the calcium oxalate filtered off as rapidly as possible. The water must also be distilled off quickly from the filtrate at the lowest possible temperature and pressure. The residual gum may then be transformed into the β -lactone by prolonged heating under 20 mm. pressure at first at 50° , but finally up to 100° .

The β -lactone, which was used to determine constants and to perform various experiments (see below), was prepared from free *d*-mannonic acid obtained from barium *d*-mannonate by rapid treatment with dilute sulfuric acid at 95° to 98° . The salt was prepared by dissolving *d*-mannonic γ -lactone in a dilute solution of one and one-half times the calculated amount of crystallized barium hydroxide and heating for ten minutes on a boiling water bath. The calculated amount of sulfuric acid was then added to liberate mannonic acid; the solution was thereupon rapidly adjusted so that it contained only a trace of barium, filtered free from barium sulfate, cooled and distilled at 20 mm. pressure with the surrounding bath at 40 – 45° until no more moisture condensed in the neck of the flask. The resulting gum, a mixture of *d*-mannonic acid and β - and γ -lactones, is very soluble in absolute alcohol. Eight grams of γ -lactone were changed into barium *d*-mannonate by 21.28 g. barium hydroxide. The gum, obtained as described above, was kept in the flask about 15 hrs. longer and became partly crystalline. The gum that still remained dissolved readily, but the crystalline mass went into solution with considerable difficulty in 400 cc. of boiling absolute alcohol. After distilling off half of the solvent at ordinary pressure and cooling, 1.45 g. of pure β -lactone, melting at 161 – 162° , $[\alpha]_D^{20} = +111.85^\circ$, came out in transparent, octahedral crystals. Mixed crystals of β - and γ -lactones, 3.66 g., melting from 134 – 150° , were obtained in four subsequent fractions on further concentration of the alcoholic filtrate.

Another experiment was carried out with 11 g. of γ -lactone in the same way, but here the adjustment for barium was made in one-half an hour,

¹ *Ann.*, 403, 314 (1914).

² *Ibid.*, 403, 310 (1914).

i. e., more quickly than in the former experiment. The residual gum, after standing about 36 hrs. also became partly crystalline, and solution was effected with difficulty by 500 cc. of boiling absolute alcohol. After filtering off traces of barium salt, the solution was concentrated to about 300 cc. by distillation at 20 mm. pressure, and in the course of two days 4.48 g. of β -lactone, melting between 156° and 162° , separated out without seeding. The filtrate was concentrated to about 100 cc. and 1 g. of impure γ -lactone was obtained, which, recrystallized from 100 cc. of absolute alcohol, gave 0.65 g. melting at 149.5° with $[\alpha]_D^{20} = +57.05^{\circ}$.

The following analytical results, molecular weight determination, specific rotation and other data were obtained with a preparation of pure β -lactone melting, after a second crystallization from absolute alcohol, between 161° and 162° . The β -lactone requires about 100 parts of boiling absolute alcohol for solution, from which, on standing at room temperatures, a very large amount crystallizes out unchanged in transparent, measurable octahedra. This lactone can be recrystallized from water, but this is not an advantageous process since an aqueous solution changes rapidly, even at 20° , to free *d*-mannonic acid.

0.2083 g. gave 0.3096 g. CO_2 and 0.1072 g. H_2O .

Calc. for $\text{C}_6\text{H}_{10}\text{O}_6$: C, 40.45; H, 5.62; found: C, 40.53; H, 5.72.

A titration was carried out as follows: the lactone was dissolved in an excess of 0.1 *N* KOH and the solution heated on a boiling water bath for 10 min. to form completely the potassium salt. The cooled solution was titrated back with 0.1 *N* H_2SO_4 (phenolphthalein as indicator) to excess, whereupon carbon dioxide was expelled by boiling. The solution, cooled again, was adjusted to the end point with 0.1 *N* KOH. 0.5051 g. used 28.26 cc. 0.1 *N* KOH instead of 28.36 cc. calculated for $\text{C}_6\text{H}_{10}\text{O}_6$.

A molecular weight determination was carried out according to the boiling point method of McCoy¹ with 0.3552 g. substance in freshly prepared absolute alcohol.²

Av., 185.3

The specific rotation of the β -lactone in 4% solution was found to be $+111.85^{\circ}$ six minutes after solution, for 0.4021 g. dissolved in 10.0456 g. of water gave $+4.35^{\circ}$ in a one decimeter tube. The specific gravity of the solution was considered 1.011, as were all subsequent 4% aqueous solutions. Observations were made with this tube kept at room temperature for 23 days to follow the changes in optical activity.

¹ *Am. Chem. J.*, 23, 353 (1900).

² The absolute alcohol used here and later was freshly prepared by redistillation over quick-lime. A middle fraction was used after standardization by determination of the molecular weight of benzoic acid.

TABLE I.

Time after solution.	Observed angle.	$[\alpha]_D$.
6 min.	+4.35°	+111.85°
1 hr. 40 min.	+3.95°	+101.54°
3 hr. 40 min.	+3.30°	+84.84°
5 hr. 30 min.	+2.53°	+65.03°
20 hr.	+1.18°	+30.28°
1 day 2 hr.	+1.15°	+29.57°

15 days	+1.20°	+30.85°
23 days	+1.55°	+39.85°

When the specific rotation reached +28.28°, the solution evidently contained in equilibrium about 25% of β -lactone together with about 75% of free *d*-mannonic acid. Traces of γ -lactone were also present. At this point 70% of the original β -lactone can be recovered, either by evaporation of the aqueous solution over H_2SO_4 *in vacuo* or by rapid distillation at 20 mm. pressure with the bath at 40°. Thus a solution of 8.1 g. of β -lactone in 32.4 g. of water which stood for 24 hrs. was freed from water by distillation at 20 mm. pressure with the surrounding bath at 35–40°. Before all the water was removed crystals separated out; the crystalline residue was loosened and removed from the flask with 100 cc. of cold, absolute alcohol. The crystals thus obtained, 6.58 g., melted between 138° and 155° and gave $[\alpha]_D^{20} = +101.33^\circ$, or, after 29 hrs. standing at ordinary temperatures, +32.18°; this showed that the mixed crystals contained about 90%, 5.9 g., of β -lactone. Furthermore, the alcoholic filtrate gave, after removing the solvent by distillation at 20 mm. pressure, 1.38 g. of solid residue, which yielded, on recrystallization from 25 cc. of warm, absolute alcohol (60°), 0.7 g. of mixed crystals melting between 132° and 142° with $[\alpha]_D^{20} = +77.1^\circ$, and containing, therefore, about 40% of β -lactone (0.28 g.). 6.2 g. or 76.54% of the β -lactone was therefore recovered unchanged.

Judging from the optical activity of an aqueous solution of β -lactone at the end of 23 days (+39.85°), as shown in Table I, about 50% of *d*-mannonic γ -lactone must now have been present, since the specific rotation of pure γ -lactone is +51.8°, whereas equilibrium exists between *d*-mannonic acid and *d*-mannonic β -lactone at +28.28°. The abnormal γ -lactone is, therefore, slowly formed from free *d*-mannonic acid by loss of water, and since this reaction, according to observations on pure γ -lac-

Small amounts of hydrogen chloride or of free *d*-mannonic acid facilitate very much the addition of the reagent. Since, however, the ester is easily converted by intramolecular addition and subsequent loss of alcohol into *d*-mannonic γ -lactone,

a reaction which is also enormously accelerated by the presence of hydrogen chloride or of free *d*-mannonic acid, it is possible to prepare pure ethyl *d*-mannonate only under very definite conditions.

As a result of certain experiments (see below), from which mixed crystals of *d*-mannonic γ -lactone and of ethyl *d*-mannonate were obtained, a method for preparing the ethyl ester quantitatively from the β -lactone was developed as follows: 62 g. of the well-powdered β -lactone were covered in a stoppered flask with 200 cc. of cold absolute alcohol containing 1% of dry hydrogen chloride, and the mixture was thoroughly shaken. Within 25 minutes the compact β -lactone was replaced by a bulky mass of filamentous crystals. The mixture was allowed to stand, however, for 24 hrs., when the crystals were filtered off and thoroughly washed free from hydrogen chloride by cold absolute alcohol. 1.04 g. melting at 158–159° were obtained; on crystallizing a portion of these, 0.53 g., from 60 cc. of hot absolute alcohol, 0.38 g. of the pure, optically inactive product, melting at 160–161°, was recovered. No more ethyl ester could be obtained from the alcoholic filtrates containing hydrogen chloride by removal of the alcohol at reduced pressure, for the solid residue, 1.28 g., now gave, on rinsing with a small amount of absolute alcohol, 0.72 g. of insoluble crystals melting between 148° and 151° with $[\alpha]_D^{20} = +49.21^\circ$. These evidently consisted of almost pure γ -lactone produced from the ester by decomposition by the hydrogen chloride.

A better yield was subsequently obtained by using 2.25 g. of β -lactone and only 100 cc. of cold 1% alcoholic hydrogen chloride; the crude, insoluble product, 2.12 g., melted between 155° and 157° and gave by crystallization from 200 cc. of absolute alcohol 1.49 g. of pure ester melting from 160–161°.

The ethyl ester can moreover only be obtained from *d*-mannonic γ -lactone by its preliminary conversion into free *d*-mannonic acid and β -lactone. The β -lactone then adds alcohol as described above. Thus 2 g. of the γ -lactone were dissolved in one and one-half times the calculated volume

of normal sodium hydroxide solution, 16.86 cc., and the solution was warmed to form the sodium salt. Then, after cooling, an equivalent amount of normal hydrochloric acid was added; the water was distilled off at 20 mm. pressure with the bath at 40°. A gum containing sodium chloride was left, which weighed 3.41 g. and of which 3.04 g. dissolved in 80 cc. of hot absolute alcohol. Concentrated alcoholic hydrogen chloride was added to make the solution contain 1% of hydrogen chloride, and 0.74 g. of ester melting at 160–161° was obtained.

The following analysis, molecular weight determination and the data on the action of water and heat were obtained by the use of a pure preparation of ethyl *d*-mannonate melting at 160–161°:

0.1728 g. gave 0.2709 g. CO₂ and 0.1115 g. H₂O.

Calc. for C₈H₁₆O₇: C, 42.87; H, 7.14; found: C, 42.76; H, 7.17.

The molecular weight was determined with 0.5083 g. substance in boiling absolute alcohol by McCoy's method; the average of three readings (232, 243, 246) was 240 instead of 224 calculated for C₈H₁₆O₇.

Pure ethyl *d*-mannonate, which is very soluble in water, has no optical activity; but the solution becomes faintly dextrorotatory within five hours, due to hydrolysis of the ester, and to the subsequent change of free *d*-mannonic acid into β - and γ -lactones, *e. g.*, 0.4163 g. of substance in 10.0653 g. of water showed no activity in a one decimeter tube, but the Table II records a series of readings which show the changes wrought by the transformation of the ethyl ester.

TABLE II.

Time after solution.	Observed angle.	$[\alpha]_D$.
5 hrs. 10 min.	+0.15°	+ 3.53°
1 day	+0.22°	+ 5.48°

5 days	+0.65°	+16.16°
6 days	+0.70°	+17.44°
7 days	+0.75°	+18.68°
8 days	+0.80°	+19.93°
10 days	+0.85°	+21.17°
16 days	+1.08°	+26.90°
26 days	+1.15°	+28.65°

If the specific rotation at the end of 26 days be calculated on the basis of lactone produced by hydrolysis (0.4163 g. of ester gives 0.3308 g. of lactone), it becomes +35.74°, which is in fair agreement with the optical activity (+39.85°) of a solution of β -lactone, or of free *d*-mannonic acid, at the end of 23 days (see above).

It is evident from the data given, and this was also proved by special experiment, that the ester can be recovered unchanged from an aqueous solution, if the water be removed within an hour; thus, 0.3711 g. of ester

in 8.9664 g. H_2O showed no optical activity; the solvent was distilled off at once at 20 mm. pressure with the bath at 40° . The residue was crystallized from 10 cc. of absolute alcohol and 0.24 g. of ester, melting at $160\text{--}161^\circ$, was recovered.

The ester is rapidly converted into γ -lactone by loss of ethyl alcohol, perhaps with intermediate formation of β -lactone (see above) when heated in a distilling flask under reduced pressure just above its melting point. One gram of ester, heated between 162° and 170° for about one-half an hour, lost 0.24 g. in weight. The stiff residual gum, 0.76 g. re-crystallized from about 10 cc. of absolute alcohol, gave 0.37 g. *d*-mannonic γ -lactone which melted between 150° and 154° with $[\alpha]_D^{20} = +51.52^\circ$. A second experiment with 1.2 g. ester, which was heated at 164° for 50 mins., gave 0.93 g. hard gum from which 0.63 g. *d*-mannonic γ -lactone, melting at $151\text{--}152^\circ$ and with $[\alpha]_D^{20} = +48.25^\circ$ was obtained.

Ethyl *d*-mannonate, which is optically inactive, and *d*-mannonic γ -lactone ($[\alpha]_D^{20} = +51.8^\circ$) give a large number of mixed crystals melting from $135\text{--}155^\circ$, the specific rotations of which naturally fall between those of the pure substances and remain constant for some hours. For a long time Nef and I thought that a third monomolecular lactone of *d*-mannonic acid was present in these mixtures, but they all gave an iodoform test due to the presence of ethyl *d*-mannonate.

Thus, a solution of 0.5 g. of β -lactone in 100 cc. of absolute alcohol containing a small amount of dry hydrogen chloride was heated at about 75° under a reversed condenser for two hours. The alcohol was distilled off at 20 mm. pressure with the temperature of the surrounding bath between 30° and 35° ; the residue was then crystallized from 30 cc. of absolute alcohol. The needles obtained, 0.2 g., melted at 139° , and gave $[\alpha]_D^{20} = +35.88^\circ$ without change after 24 hrs. standing.

Again, 1 g. of β -lactone and 30 cc. of absolute alcohol, heated in a sealed tube at 120° for 5 hrs., gave 0.83 g. of concentric needles, melting between 140° and 142° with $[\alpha]_D^{20} = +45.63^\circ$; the product was, therefore, mainly *d*-mannonic γ -lactone mixed with about 10% of ethyl ester.

A preparation consisting of mixed crystals of *d*-mannonic β - and γ -lactones (the melting point and specific rotation of which had not been determined) when treated with cold absolute alcohol containing a small amount of dry hydrogen chloride, soon deposited bulky, apparently homogeneous crystals melting at $140\text{--}141^\circ$, the specific rotation of which remained constant in aqueous solution at $+24.8^\circ$.

Nef¹ and Lewis obtained many such mixed crystals when working with mixtures of *d*-mannonic acid and *d*-mannonic β - and γ -lactones both in the presence and absence of hydrogen chloride.

Finally it should be especially emphasized that pure *d*-mannonic γ -lac-

¹ *Ann.*, 403, 310 (1914).

tone, treated with the concentrated sulfuric acid-chloride, gives no ethyl ester.

***d*-Mannonic γ -Lactone.**—This lactone was discovered by Fischer and Hirschberger,¹ but it was contaminated with β -lactone so that it melted over a range, 149–153°, and showed a high specific rotation, +53.81°, in 10% concentration. Nef² has shown that the pure γ -lactone melts sharply at 151° and gives $[\alpha]_D^{20} = +51.8^\circ$ in 4% concentration; this lactone moreover remains unchanged in aqueous solution at 20° for a long time, whereas the far more strongly active β -lactone, $[\alpha]_D^{20} = +111.85^\circ$, is rapidly hydrolyzed to mannonic acid (a gum very soluble in cold absolute alcohol, $[\alpha]_D^{20} = -1^\circ$) to the extent of 75%, at which point the β -lactone exists in equilibrium at 20° with the free acid. Since the γ -lactone has repeatedly been analyzed and titrated, it was only necessary to make a molecular weight determination and thus prove that the substance is monomolecular. The determination was made with McCoy's boiling point apparatus, using absolute alcohol as the solvent, in which it is far more soluble than the β -lactone.

0.5391 g. of lactone gave 199 for the molecular weight instead of 178 calculated for $C_6H_{10}O_6$.

The γ -lactone reacts with water when heated in aqueous solution at 100°. *d*-Mannonic acid is first formed, from which the β -lactone is then produced; its presence can easily be proved since the specific rotation of the solution decreases in a few hours. The following experiments illustrate these changes: An approximately 4% solution of γ -lactone (0.5480 g. in 13.5908 g. H_2O), when heated for one hour on a boiling water bath and cooled quickly with running water, gave at first a specific rotation of +50.53° ($\alpha = +1.98^\circ$ in a 1 dc. tube); this became +48.5° after 72 hrs. standing at room temperatures. Another experiment, in which an aqueous solution of γ -lactone was heated for five hours on a boiling water bath, gave on rapid cooling a specific rotation of +51.22° (0.5311 g. in 13.0843 g. H_2O gave $\alpha = +2.02^\circ$ in a 1 dc. tube); this fell after 15 hrs. to +46.91°. The solution, evaporated over H_2SO_4 *in vacuo*, yielded a solid residue, 0.5374 g, melting between 132° and 148°; 0.4933 g. of this dissolved in 10.5960 g. H_2O gave a specific rotation of +59.14° ($\alpha = +2.66^\circ$ in a 1 dc. tube); after 40 hrs. standing this had fallen to +46.69°. Evidently more β -lactone was formed from free *d*-mannonic acid, also at first present, which accounts for the higher specific rotation of the solid residue.

² *Ann.*, 403, 316 (1914).

II. On Ethyl *d*-Gluconate and on *d*-Gluconic β - and γ -Lactones.

Nef presents with great precision in his *Annalen* paper¹—the end result of years of experimental work—the most favorable conditions, A, for the conversion of free *d*-gluconic acid (a viscous syrup, $[\alpha]_D^{20} = -1.7^\circ$, very soluble in cold absolute alcohol), or of *d*-gluconic β -lactone into ethyl *d*-gluconate (bulky, fibrous crystals, $[\alpha]_D^{20} = -1^\circ$, melting between 60° and 65°); B, for the transformation of free *d*-gluconic acid or of ethyl *d*-gluconate into normal *d*-gluconic β -lactone (transparent prisms, $[\alpha]_D^{20} = +61.7^\circ$, melting point 152° , and soluble in 100 parts of boiling absolute alcohol); and finally, C, for the conversion of any of these three substances at higher temperatures into the abnormal and more stable *d*-gluconic γ -lactone (heavy needles, melting from 134 – 136° , $[\alpha]_D^{20} = +67.8^\circ$, and soluble in 14 parts of hot absolute alcohol). The situation in this series is complicated by the fact that here alone, among all the polyhydroxy acids $C_nH_{2n}O_{n+1}$ as yet studied, a very marked tendency to polymolecular anhydride formation is noticeable. This phenomenon is due, as Nef has shown, to an intermediate formation of *nascent* monomolecular *d*-gluconic α -lactone,² $CH_2OH(CHOH)_4CH-C=O$.

The study of these polygluconic anhydrides, which are precipitated from aqueous solution by alcohol, is at present being continued in this laboratory and has been found to present great experimental difficulties; I have consequently limited myself mainly to a further study of the physical and chemical properties of ethyl *d*-gluconate, and of the monomolecular β - and γ -lactones of *d*-gluconic acid.

***d*-Gluconic β -Lactone.**—The new, normal β -lactone has been obtained both from free *d*-gluconic acid and from ethyl *d*-gluconate (see this).

Nef² has given precise directions whereby a yield of about 20% of β -lactone can be obtained from anhydrous calcium *d*-gluconate.

I prepared *d*-gluconic β -lactone from free *d*-gluconic acid by treatment of a warm (60°), aqueous solution of 10 g. of anhydrous calcium *d*-gluconate with 2.93 g. of crystallized oxalic acid in water. The solution of *d*-gluconic acid, cooled at once to 20° and filtered, was freed from water by distillation at 20 mm. pressure with the surrounding bath at 40° , until a syrup, containing about 10 g. of water, resulted, whereupon 100 cc. absolute alcohol were added to precipitate traces of calcium salt as well as polygluconic anhydrides. The residual gum, 8.18 g., obtained from the filtrate by removal of water and alcohol at reduced pressure, yielded, on dissolving in about 10 cc. warm absolute alcohol, 1.04 g. β -lactone (in two fractions) melting from 151 – 154° ; this, recrystallized from 25 cc.

¹ *Ann.*, 403, 322–331 (1914).

² *Ibid.*, 403, 322 (1914).

³ *Ibid.*, 403, 323–325 (1914).

absolute alcohol, gave 0.75 g. pure β -lactone melting at 63.4° five minutes after solution.

th $[\alpha]_D^{20} =$

The following constants and analyses were obtained with comparisons of pure β -lactone:

comparisons

0.1237 g. gave 0.1855 g. CO_2 and 0.0566 g. H_2O .

Calc. for $\text{C}_6\text{H}_{10}\text{O}_6$: C, 40.45; H, 5.92; found: C, 40.90; H, 5.13.

The titration was carried out as previously described. 0.4227 g. substance used 23.61 cc. 0.1 *N* KOH instead of 23.75 cc. calculated for $\text{C}_6\text{H}_{10}\text{O}_6$.

The molecular weight of β -lactone, determined by the boiling point method in McCoy's apparatus (see *d*-mannonic β -lactone) using absolute alcohol and 0.4801 g. substance, was found to be 199.3 instead of 178 calculated for $\text{C}_6\text{H}_{10}\text{O}_6$.

Mol. wt.	100	199.3

Nef¹ found the specific rotation of *d*-gluconic β -lactone at 20° to be +61.7° twelve minutes after solution. The specific rotation was found by me to be +63.4° five minutes after solution (0.4288 g. dissolved in 9.4233 g. H_2O at 20° gave $\alpha = +2.79^\circ$ in a 1 dc. tube). The changes in optical activity of this solution for nearly eight days (after which constancy ensued) are recorded in Table III.

TABLE III.

Time after solution.	Observed angle.	$[\alpha]_D$.	Time after solution.	Observed angle.	$[\alpha]_D$.
5 min.	+2.79°	+63.40°	46 min.	+1.64°	+37.25°
7 min.	+2.75°	+62.50°	59 min.	+1.27°	+29.13°

14 min.	+2.60°	+60.47°	1 hr. 45 min.	+0.67°	+15.23°
17 min.	+2.54°	+59.05°	2 hr. 20 min.	+0.50°	+11.36°
18½ min.	+2.50°	+58.13°	2 hr. 35 min.	+0.45°	+10.21°
19 min.	+2.47°	+57.44°	16 hr. 50 min.	+0.47°	+10.64°
22 min.	+2.35°	+53.40°	22 hr. 50 min.	+0.52°	+11.82°
24 min.	+2.30°	+52.26°	26 hr. 35 min.	+0.52°	+11.82°
26 min.	+2.25°	+51.13°	47 hr. 50 min.	+0.62°	+14.09°
35 min.	+1.97°	+44.77°	3 days 18 hr.	+0.76°	+17.27°
			7 days 21 hr.	+0.90°	+20.45°

From this table it is clear that *d*-gluconic β -lactone is converted in two and one-half hours at 20° to the extent of nearly 80% into free *d*-gluconic acid ($[\alpha]_D^{20} = -1.7^\circ$). It should be especially noticed that temporary equilibrium was maintained with $[\alpha]_D^{20} = +11^\circ$ for 24 hrs.²

¹ *Ann.*, 403, 325 (1914).

² According to Nef (*Ann.*, 403, 326 (1914)) aqueous solutions of β -lactone reach $[\alpha]_D^{20} = +9.94^\circ$ after 2½ hrs. standing at 20°; $[\alpha]_D^{20} = +7.71^\circ$ after 4½ hours; a minimum at $[\alpha]_D^{20} = +6.24^\circ$ after 26 hrs.; $[\alpha]_D^{20} = +7.95^\circ$ after 46 hrs.; $[\alpha]_D^{20} = +9.69^\circ$ after 70 hrs.; and $[\alpha]_D^{20} = +9.94^\circ$ after 114 hrs.

Dr. Nef suggests that the values for the specific rotation lower than +9.94° may be inaccurate due to fatigue of his research assistant's eyes.

Final equilibrium at 20° in 4% aqueous solutions of *d*-gluconic acid, as well as of β - and γ -lactones, is, however, only reached, when the specific rotation has become about +18° (see below). Such solutions, heated for five hours on a boiling water bath and then quickly cooled, give at first a specific rotation of +32° to +34°, which changes on long standing to about +18°.

Thus, a solution of 0.5748 g. β -lactone in 14.8255 g. H₂O, heated for one hour on a boiling water bath and then cooled rapidly, gave $[\alpha]_D^{20} = +28.89^\circ$ ($\alpha = +1.09^\circ$ in a 1 dc. tube); $[\alpha]_D^{20}$ fell to +25.17° after 2³/₄ hrs., and to +23.05° after 24 hrs. standing at room temperatures. In a second experiment a solution of 0.5075 g. β -lactone in 13.0649 g. H₂O, heated for five hours on a boiling water bath and cooled rapidly, gave $[\alpha]_D^{20} = +32.51^\circ$ ($\alpha = +1.23^\circ$ in a 1 dc. tube); $[\alpha]_D^{20}$ fell to +26.91° after 16³/₄ hrs. and to +17.72° after 15¹/₂ days standing at room temperatures. This solution must have contained at first ($[\alpha]_D^{20} = +32.51^\circ$) about 50% of β - and γ -lactones of which 8 to 12% was β -lactone, for an aqueous solution, originally containing pure *d*-gluconic γ -lactone (cf. Table V), gave, after standing 4³/₄ days at room temperatures, $[\alpha]_D^{20} = +33.98^\circ$; this fell to +26.46° after 48 hrs. further standing at room temperatures.

It is consequently obvious from the data presented that the situation here is entirely analogous to that observed in the case of free *d*-mannonic acid and its β -lactone. An aqueous solution of free *d*-gluconic acid (see below) or of *d*-gluconic β -lactone rapidly reaches an equilibrium with the specific rotation +10° or +11°; since, however, abnormal γ -lactone formation also takes place, but extremely slowly at 20°, there is a gradual rise in the specific rotation of such solutions until a limit is reached with $[\alpha]_D^{20} = +18^\circ$. There is in the present case no irreversible and complete transformation into γ -lactone, because *d*-gluconic γ -lactone is, in contrast to *d*-mannonic γ -lactone, slowly acted upon by water at 20°.

Ethyl *d*-Gluconate.—This ester crystallizes from absolute alcohol, in which it is very soluble, in bulky, fibrous needles; these contain, air-dried, much alcohol of crystallization and melt from 40–50°; after standing over H₂SO₄ *in vacuo*, they lose the alcohol and melt between 62° and 63°. I observed no optical activity in a 4% aqueous solution of the ester, whereas Nef¹ obtained $[\alpha]_D^{20} = -0.997^\circ$.

The ester is formed by the addition of ethyl alcohol to the active molecules of *d*-gluconic β -lactone (cf. ethyl *d*-mannonate) in the presence of small quantities of the free *d*-gluconic acid or hydrogen chloride. In many experiments large amounts of ester were obtained by dissolving a residual gum, consisting of *d*-gluconic acid and of β - and γ -lactones, in boiling absolute alcohol, whereupon the alcohol was removed at reduced pressure, until a thin syrup remained; this would then, on standing, be spontaneously

¹ *Ann.*, 403, 327 (1914).

transformed into a mass of crystals of γ -lactone and of ethyl ester, which could easily be separated by fractionation from absolute alcohol.

The ethyl ester was also obtained in the following definite way: A solution of free *d*-gluconic acid, obtained from 9.53 g. anhydrous calcium *d*-gluconate and 2.73 g. crystallized oxalic acid, was digested a few moments on a boiling water bath, cooled, and filtered free from calcium oxalate. The water was removed from the filtrate by distillation at 20 mm. pressure, with the residue remaining a thick, gummy mass. This gum, 7.13 g., was heated for five hours at 150° (oil bath at 152.1°) dissolved, on shaking, in 100 cc. of cold absolute alcohol; after concentration to about 25 cc., one drop of 17.25 *N* alcoholic hydrogen chloride was added to this solution, which was then warmed to 50° for about 3 mins., whereupon it was cooled by running water. After standing 20 hrs., 1.25 g. ethyl ester, melting (after drying over H_2SO_4 *in vacuo*) between 62° and 63°, separated out.

Analysis and physical constants of ethyl *d*-gluconate:

0.1997 g. gave 0.3123 g. CO_2 and 0.1267 g. H_2O .

Calc. for $C_8H_{16}O_7$: C, 42.83; H, 7.20; found: C, 42.65; H, 7.12.

The molecular weight of β -lactone, determined by the boiling point method in McCoy's apparatus (see above) using 0.5811 g. substance dissolved in absolute alcohol, was found to be 252 instead of 224 calculated for $C_8H_{14}O_7$.

			Av. 252

No optical activity was observed at first on dissolving 0.57 g. ethyl ester in 12.48 g. H_2O ; the solution became optically active, however, on standing at room temperatures through hydrolysis of the ester and subsequent conversion of free *d*-gluconic acid into β - and γ -lactones.

Time after solution.	Observed angle.	$[\alpha]_D$.
6 days	+0.35°	+ 7.60°
10 days	+0.46°	+ 9.98°
17 days	+0.50°	+10.85°

If the specific rotation at the end of 17 days be calculated on the basis of lactone produced by hydrolysis (0.57 g. ester gives 0.453 g. lactone), it becomes +14.25°, which is in fairly close agreement with the region of equilibrium, +18°, reached by aqueous solutions of free *d*-gluconic acid and of *d*-gluconic β - and γ -lactones on long standing at ordinary temperatures.

The following further experiments with ethyl *d*-gluconate are interesting since they show that the β -lactone can be obtained from the ester to the extent of about 30% by simply heating in a distilling flask under 20 mm. pressure in a bath kept between 70° and 80° for 10 hrs.; a small amount of polygluconic anhydrides is also formed, as well as some γ -lactone. The γ -lactone could probably be obtained to the extent of 70% or more

by raising the temperature of the surrounding bath to 130–140° during the experiment. Thus, after 3 g. of ethyl *d*-gluconate had been heated at 70–80° as described, with a loss in weight of 0.52 g., a partly crystalline mass remained in the distilling flask from which 1.03 g. crude β -lactone, melting from 140–152°, were obtained. In a second experiment 3.7 g. ester lost 0.55 g. in weight; the residual partly crystalline mass yielded 0.94 g. β -lactone melting from 152–153.5°.

***d*-Gluconic Acid.**—This acid, $C_6H_{12}O_7$, has been obtained only as a syrup ($[\alpha]_D^{20} = -1.7^\circ$), very soluble in absolute alcohol, and is transformed in aqueous solution at ordinary temperatures mainly into β -lactone, but at 100° largely into γ -lactone; at all temperatures, however, equilibrium is established in aqueous solution with a definite percentage of these three components present.

In order to determine when equilibrium is reached in aqueous solutions at 20°, *d*-gluconic acid was prepared from a warm (60°) aqueous solution of 10 g. anhydrous calcium *d*-gluconate (corresponding to 9.19 g. $C_6H_{12}O_7$) by treatment with 2.93 g. crystallized oxalic acid in water also at 60°. Immediately after mixing, the solution of *d*-gluconic acid was cooled within one minute to 20°, filtered from calcium oxalate, and made up to 250 cc.; it gave $[\alpha]_D^{20} = +2.19^\circ$ (calculated for $C_6H_{12}O_7$) forty-five minutes after cooling ($\alpha = +0.16^\circ$ in a 2 dc. tube; $c = 3.647$). The following subsequent observations were made with the same tube kept at room temperatures. The calculations for the specific rotation are here, however, based on the theoretical amount of lactone, 8.28 g., obtainable from 10 g. anhydrous calcium *d*-gluconate. Equilibrium was finally reached with the specific rotation about $+18^\circ$.

TABLE IV.

Time after cooling the solution.	Observed angle.	$[\alpha]_D$.
45 min.	$+0.16^\circ$	$+2.42^\circ$
2 hrs.	$+0.45^\circ$	$+6.80^\circ$
20 hrs.	$+0.65^\circ$	$+9.82^\circ$
1 day 23 hrs.	$+0.65^\circ$	$+9.82^\circ$
3 days	$+0.77^\circ$	$+11.63^\circ$
4 days	$+0.81^\circ$	$+12.24^\circ$
5 days	$+0.96^\circ$	$+14.50^\circ$
7 days	$+1.05^\circ$	$+15.85^\circ$
11 days	$+1.17^\circ$	$+17.67^\circ$

From Table IV it is evident that a condition of temporary equilibrium was maintained with the specific rotation at about $+10^\circ$ for 27 hrs.; this is in fairly close agreement with the region of temporary equilibrium ($+11^\circ$), reached after an aqueous solution of *d*-gluconic β -lactone (see above) has stood for two and one-half hours at ordinary temperatures.

According to observations published by Schnelle and Tollens,¹ an

¹ *Ann.*, 271, 74 (1890); *Ber.*, 23, 2991 (1890).

aqueous solution of free *d*-gluconic acid reaches equilibrium with the specific rotation between $+10^\circ$ and $+12^\circ$ after standing two or three weeks at room temperatures.

Equilibrium at $96-98^\circ$ was found thus: a solution of *d*-gluconic acid, prepared from 10 g. anhydrous calcium *d*-gluconate (corresponding to 8.28 g. lactone), was heated for $13\frac{1}{2}$ hrs. on a boiling water bath; quickly cooled this gave $[\alpha]_D^{20} = +32.46^\circ$ calculated on the basis of $C_6H_{10}O_6$, ($\alpha = +2.14^\circ$ in a 2 dc. tube; $c = 3.312$); $[\alpha]_D^{20}$ fell to $+25.52^\circ$ after $15\frac{1}{2}$ hrs. and to $+17.96^\circ$ after 16 days' standing at room temperatures. *d*-Gluconic β -lactone as well as far more γ -lactone must have been present at the end of $13\frac{1}{2}$ hrs. heating.

***d*-Gluconic γ -Lactone.**—This abnormal lactone has been obtained by E. Fischer¹ in practically pure condition. He recrystallized the lactone twice from small amounts of water and found that it melted between 130° and 135° , and gave $[\alpha]_D^{20} = +68.2^\circ$ in 8% concentration, or after 24 hrs. standing $+64.13^\circ$. No β -lactone could therefore have been present. Schnelle and Tollens² describe a preparation, melting from 122° to 125° , which gave $[\alpha]_D^{20} = +61.59^\circ$ ten minutes after solution, and eight minutes later $+58.83^\circ$, in about 8% concentration; therefore a small amount of β -lactone was present. Nef³ found the melting point of a preparation of pure γ -lactone, twice crystallized from 14 parts of absolute alcohol, to be $133-135^\circ$ with $[\alpha]_D^{20} = +67.82^\circ$ (in 4% concentration). I obtained γ -lactone, recrystallized from eight parts of absolute alcohol, melting from 134° to 136° with $[\alpha]_D^{20} = +67.52^\circ$ (in 4% concentration).

Many experiments were carried out to determine the best conditions for obtaining the γ -lactone; the best of these with the results follow. When a solution of *d*-gluconic acid, of slightly less than 4% concentration, was heated for $13\frac{1}{2}$ hrs. on a boiling water bath (cf. *d*-gluconic acid), the specific rotation became $+32.46^\circ$, indicating the presence of a large amount, perhaps 45 to 50%, of γ -lactone, besides a much smaller amount of β -lactone.

In another experiment the aqueous filtrate, obtained from 26.33 g. anhydrous calcium *d*-gluconate (corresponding to 21.8 g. lactone) by treatment with the calculated amount of crystallized oxalic acid, 7.115 g., was heated for only one hour on a boiling water bath and then allowed to reach room temperature by standing one hour longer, with final cooling at 20° . This filtrate made up to 640 cc. with water gave $[\alpha]_D^{20} = +16.99^\circ$, calculated on the basis of $C_6H_{10}O_6$ ($\alpha = +1.21^\circ$ in a 2 dc. tube; $c = 3.406$). The water was now removed from the solution 20 hrs. later by distillation at 20 mm. pressure with the surrounding bath at 50° , until no more mois-

¹ *Ber.*, 23, 2625 (1890).

² *Ann.*, 271, 76 (1892).

³ *Ibid.*, 403, 330 (1914).

ture condensed in the neck of the flask, whereupon the gum, 21.3 g., gave $[\alpha]_D^{20} = +22.94^\circ$, calculated on the basis of $C_6H_{10}O_6$ ($\alpha = +2.00^\circ$ in a 2 dc. tube; $c = 4.26$); $[\alpha]_D^{20}$ fell to $+17.77^\circ$ after 50 hrs. standing at room temperatures. The amount of lactone in the gum was therefore very little more than that in solution before the above distillation. After removing the water again by distillation at 20 mm. pressure with the surrounding bath at 70° , the residual gum, heated two hours longer at 90° , now weighed 19.5 g. and gave $[\alpha]_D^{20} = +52.82^\circ$, calculated on the basis of $C_6H_{10}O_6$, fifteen minutes after solution ($\alpha = +10.3^\circ$ in a 2 dc. tube; $c = 9.75$); this fell to $+28.72^\circ$, after standing 19 hrs. at room temperatures, showing that, besides a large amount of γ -lactone, much β -lactone was present.

These data make it perfectly clear that the most ideal way, in which to obtain a maximum yield of *D*-gluconic γ -lactone from anhydrous calcium *D*-gluconate, is to precipitate the calcium with the calculated amount of crystallized oxalic acid, and thereupon to heat the aqueous solution of free *D*-gluconic acid for 12 hrs. on a boiling water bath. At least 50% of the acid will be transformed into the β - and γ -lactones. The water must then be removed by distillation at 50 mm. pressure, while the temperature of the surrounding bath is kept between 90° and 100° . In this way at least 80% of γ -lactone should be obtained.

An attempt to prepare γ -lactone by heating a residual gum *in vacuo* to 130° proved successful. Under these conditions a larger amount than usual was produced. Thus, an aqueous solution of *D*-gluconic acid, prepared from 15 g. anhydrous calcium *D*-gluconate by treatment with 4.4 g. crystallized oxalic acid, was heated for one hour on a boiling water bath and filtered from calcium oxalate. The water was removed from the filtrate by distillation at 20 mm. pressure with the surrounding bath at 45° , whereupon the syrup was heated in an oil-bath at 130° for $4\frac{1}{2}$ hrs. The residual light brown gum, 11.58 g., was resolved by 200 cc. boiling absolute alcohol into two portions, A, 2.98 g. insoluble polygluconic anhydrides, and B, 8.6 g. soluble gum which dissolved in 50 cc. absolute alcohol yielded 1.98 g. crude γ -lactone, melting from 133° to 137° , with $[\alpha]_D^{20} = +67.05^\circ$ (seven minutes after solution); this fell to $+55.66^\circ$ after five hours' standing at room temperatures. There was, therefore, a small amount of β -lactone present (cf. rate of change of β - and γ -lactones).

E. Fischer and others have analyzed *D*-gluconic γ -lactone; therefore only the following additional data on this substance were ascertained:

0.4761 g., dissolved in excess of 0.1 *N* KOH heated 10 mins. on a boiling water bath and titrated back with 0.1 *N* H_2SO_4 , used 26.84 cc. 0.1 *N* KOH instead of 26.75 cc. calculated for $C_6H_{10}O_6$.

A molecular weight determination by the boiling point method with 0.5720 g. γ -lactone dissolved in absolute alcohol, using McCoy's apparatus (see above) gave 194 instead of 178 calculated for $C_6H_{10}O_6$.

Vol. of solution, cc.	27.3	28.4	29.5	30.8	
Rise in B. P.	0.169°	0.161°	0.154°	0.151°	
Mol. wt. found.	193	195	196	191	Av. 194

The specific rotation of *d*-gluconic γ -lactone was found to be $+67.52^\circ$ at 20° nine minutes after solution (0.4190 g. in 9.8876 g. H_2O gave $\alpha = +2.78^\circ$ in a 1 dc. tube). The following subsequent observations were made with the same tube kept at room temperatures:

TABLE V.

Time after solution.	Observed angle.	$[\alpha]_D$.
50 min.	$+2.78^\circ$	$+67.52^\circ$
18 hrs.	$+2.42^\circ$	$+58.75^\circ$
21 hrs.	$+2.42^\circ$	$+58.75^\circ$
2 days 18 hrs.	$+1.83^\circ$	$+44.43^\circ$
3 days 18 hrs.	$+1.57^\circ$	$+38.12^\circ$
4 days 18 hrs.	$+1.40^\circ$	$+33.98^\circ$
6 days 18 hrs.	$+1.09^\circ$	$+26.46^\circ$
7 days 18 hrs.	$+0.98^\circ$	$+23.79^\circ$
9 days 18 hrs.	$+0.83^\circ$	$+20.15^\circ$
10 days 22 hrs.	$+0.78^\circ$	$+18.94^\circ$
13 days 22 hrs.	$+0.72^\circ$	$+17.69^\circ$

Another experiment with 1.00015 g. γ -lactone dissolved in 24.0751 g. H_2O gave $[\alpha]_D^{20} = +66.91^\circ$ twenty-five minutes after solution ($\alpha = +5.398^\circ$ in a 2 dc. tube); this fell to $+66.40^\circ$ and to $+58.35^\circ$ after standing at room temperatures for $2\frac{1}{4}$ hrs. and 24 hrs. after solution, respectively.

d-Gluconic γ -lactone reacts rapidly with water at higher temperatures; such a solution, after heating 10 hrs. at 98° , reaches equilibrium at about $+34^\circ$, as is evident from the following data: these are, moreover, in perfect agreement with the results of heating *d*-gluconic β -lactone and *d*-gluconic acid in aqueous solutions.

A solution of 0.8706 g. γ -lactone in 20.1144 g. H_2O , heated for one hour on a boiling water bath, gave, on rapid cooling to 20° , $[\alpha]_D^{20} = +40.53^\circ$ ($\alpha = +1.7^\circ$ in a 1 dc. tube); this fell to $+37.92^\circ$, to $+33.86^\circ$ and to $+18.09^\circ$ after standing 1 hr., $14\frac{1}{2}$ hrs. and 19 days, respectively, at room temperatures. Another solution of 0.4441 g. γ -lactone in 10.1686 g. H_2O , heated for five hours on a boiling water bath and then cooled rapidly, gave $[\alpha]_D^{20} = +35.09^\circ$ ($\alpha = +1.48^\circ$ in a 1 dc. tube); this fell to $+28.36^\circ$ and to $+25.76^\circ$ after standing $1\frac{1}{8}$ hrs. and $20\frac{1}{2}$ hrs., respectively, at room temperatures. A third solution of 0.4239 g. γ -lactone in 9.7897 g. H_2O , heated for ten hours on a boiling water bath, gave, on rapid cooling to 20° , $[\alpha]_D^{20} = +34.84^\circ$ ten minutes after cooling ($\alpha = +1.48^\circ$ in a 1 dc. tube); this fell to $+27.07^\circ$ and to $+18.12^\circ$ after standing 18 hrs. and 17 days, respectively, at room temperatures.

The change in optical activity between $+34.84^\circ$ and $+27.07^\circ$ (during

18 hrs.) is more rapid than the change, observed with an aqueous solution of pure *d*-gluconic γ -lactone (cf. Table V) at 20°, between +33.98° and +26.46° (during 48 hrs.); therefore considerable β -lactone must have been present.

Finally, Schnelle and Tollens¹ published long ago some observations on a crystalline lactone, obtained from free *d*-gluconic acid, to which they assign the composition $C_{12}H_{22}O_{11}$ or $C_{12}H_{20}O_{11}$. Their preparation melted between 110° and 115° and gave $[\alpha]_D^{20} = +39.07^\circ$, or $+14.84^\circ$ after standing at 19° for 52 days. 1.017 g. substance lost 0.078 g. in weight assumed without proof to be water. It is now very obvious that their product simply consisted of mixed crystals of ethyl *d*-gluconate (about 57%) and *d*-gluconic γ -lactone. Nef, as well as I, has repeatedly obtained such low melting mixed crystals which could always be resolved into the two components by further recrystallization from alcohol.

III. Ortho-bis-*d*-Galactonic Acid, *d*-Galactonic γ -Lactone and Its Monohydrate.

All attempts to prepare an ester and a monomolecular β -lactone of *d*-galactonic acid, analogous to those in the *d*-mannonic acid and *d*-gluconic acid series, have failed, although some slight evidence of the existence of a β -lactone, rapidly decomposed by water has been obtained (see below). Kohn² has prepared ethyl *d*-galactonate in combination with calcium chloride.

Pure *d*-galactonic γ -lactone, opaque prismatic needles, melting between 108° and 111° with $[\alpha]_D^{20} = -76.97^\circ$, has been prepared. This lactone is remarkable for the ease with which it adds water to form the very charac-

prisms, melting at 66° with $[\alpha]_D^{20} = -70.1^\circ$, analogous to chloral hydrate and bis-ortho oxalic acid. Both of these compounds are very soluble in water and in alcohol, but with some difficulty in ethyl acetate.

Free *d*-galactonic acid, on the other hand, is, in very marked contrast to *d*-mannonic and *d*-gluconic acids, a solid [melting between 140° and 141°, with $[\alpha]_D^{20}$ (calculated as $C_6H_{12}O_6$, see below) = -12.23°] practically insoluble in boiling absolute alcohol. It contains one-half a molecule of water of crystallization which can not be removed by prolonged drying over H_2SO_4 *in vacuo*. I therefore name it ortho-bis-*d*-galactonic acid and assign to it the bimolecular formula, $C_6H_{12}O_7 \cdot CH_2OH(CHOH)_4C(OH)_3$,

¹ *Ann.*, 271, 79 (1892).

² *Monats.*, 16, 334 (1895).

analogous to bis-ortho oxalic acid, or the more stable milk sugar hydrates, $\text{CH}_2\text{OHCHOHCH}(\text{CHOH})_2\text{—C—O—CH}_2(\text{CH}_2\text{CH}(\text{OH})_2)_2$

etc. It is monomolecular in cold aqueous solutions, and titrates with alkali hydroxides, therefore, at once in the cold for free *d*-galactonic acid.

Ortho-bis-*d*-Galactonic Acid.—This acid has already been isolated in an impure condition (melting between 122° and 125°) over 30 years ago by Kiliani,¹ and his observations have been confirmed by Schnelle and Tollu.² It was first isolated in raising the melting point of the acid obtained from water with the addition of alcohol.

I prepared the pure acid in the following way: An aqueous solution of 97.2 g. calcium *d*-galactonate (containing 4 H₂O by analysis) was treated on a boiling water bath with the calculated amount of crystallized oxalic acid, 24.4 g., in water and, after five minutes' digestion, the mixture, cooled quickly with running water, was filtered free from calcium oxalate. When the filtrate had become concentrated by distillation at 20 mm. pressure with the surrounding bath never over 50°, crystals of ortho-bis-*d*-galactonic acid separated out in large amounts; 26.79 g. of crude acid, melting between 122° and 125°, were thus obtained in two crops. These were dissolved in 77 cc. water at 60° and the filtrate was then poured into 500 cc. absolute alcohol with subsequent addition of 200 cc. absolute alcohol; 17.48 g. crystal needles (melting at 140–141°, with $[\alpha]_D^{20}$ (calculated on the basis of C₆H₁₂O₇) = –12.23°) separated out on standing. The water-alcohol filtrate, concentrated to 50 cc. at reduced pressure, yielded, on addition of 100 cc. absolute alcohol, 4.17 g. of equally pure acid.⁵

The acid loses water with great difficulty for 0.9818 g., air-dry crystals, melting at 140–141°, kept over H₂SO₄ *in vacuo*, lost only 0.0041 g. H₂O after 20 days.

Six analyses of five preparations of the substance were made; one preparation was crystallized from water alone, and the others from water and varying amounts of alcohol; the melting points of the acid obtained ranged, after drying over H₂SO₄ *in vacuo*, from 134–147°.

¹ Ber., 14, 651 (1881); *Ibid.*, 18, 1551 (1885).

² Ann., 271, 82 (1892).

³ Ber., 33, 2146 (1900).

⁴ Ann., 403, 273–275 (1914).

⁵ The mother liquor, still containing 5.1 g. substance, was united with the original aqueous filtrate from which 26.79 g. crude acid had been removed, and the combined solutions were worked up for *d*-galactonic γ -lactone and γ -lactone hydrate (see below).

	Gram.	M. p.	CO ₂ .	H ₂ O.	% C.	% H.
I	0.3168	140-1°	0.4051 g.	0.1837 g.	34.88	6.39
II	0.36375	140-1°	0.4680 g.	0.2143 g.	35.09	6.54
III	0.3199	147°	0.4105 g.	0.1837 g.	35.00	6.38
IV	0.3571	143-4°	0.4591 g.	0.2066 g.	35.06	6.43
V	0.3443	136-8°	0.4416 g.	0.1947 g.	34.98	6.35
VI	0.3235	134-6°	0.4125 g.	0.1850 g.	34.77	6.35

Calc. for C₁₂H₂₂O₁₁ 35.11 6.49

On titration with 0.1 *N* sodium hydroxide in the cold the substance behaved like a free acid; 0.4247 g. used 20.20 cc. 0.1 *N* NaOH (phenolphthalein) instead of 20.69 cc. calculated for C₁₂H₂₂O₁₁.

A molecular weight determination by the freezing point method proved that the acid, in cold aqueous solutions, is monomolecular, *i. e.*, such solutions contain either free meta *d*-galactonic acid or free ortho *d*-galactonic acid (molecular weights 196 and 214, respectively), or perhaps both. 1.1506 g. substance were used. The phenomenon of supercooling was considered in the usual way and the amount of liquid solvent, *W'*, was found by the formula

$$W' = W(1 - \frac{S.D}{L}),$$

in which *W* is the total solvent (24.879 g. H₂O), *S* is the specific heat of the solvent, *L* is the latent heat of fusion, and *D* is the supercooling.

D'.	W'.	Δ.	Mol. wt. found. ¹
0.184	24.84 g. H ₂ O	0.442°	194.9
1.674	24.12 g. H ₂ O	0.447°	198.4
1.663	24.38 g. H ₂ O	0.448°	195.9

Average, 196.4

The molecular weight determination was not corrected for ionization of the acid; this would be too small to make much increase in the observed molecular weight.

There was for a long time doubt on the question as to whether the formula of the crystalline acid was C₆H₁₂O₇·H₂O or 2C₆H₁₂O₇·H₂O, *i. e.*, whether the substance was ortho-*d*-galactonic acid or ortho-bis-*d*-galactonic acid. This was finally settled in favor of the latter formula by the following experiment: 5.06 g. ortho-bis-*d*-galactonic acid, melting at 140-141°, were heated for two hours in a small distilling flask under 20 mm. pressure with the surrounding bath at 145°; the flask was connected with a small condenser, which was joined to a receiver cooled to -16°. A slow, continuous stream of dry air was passed through the molten mass by means of a capillary tube. The amount of ice, which accumulated in the receiver, was 0.62 g. or 12.35%, whereas 0.665 g., or 13.17%, is the

¹ For preliminary practice the molecular weight of pure crystallized glucose by the freezing point method was found to be 176.7 instead of 180 for C₆H₁₂O₆.

theoretical amount of water, for $C_{12}H_{26}O_{16} = 311.10$. The molten distillate also gave no iodoform test, establishing the absence of alcohol. Finally the residue in the distillate, 4.29 g., yielded by crystallization from absolute alcohol γ -lactone, melting from 105° to 109° .

Since ortho-bis-*d*-galactonic acid exists only in the monomolecular form in aqueous solution, it should show exactly the same specific rotation as an acid just liberated from a salt. This is a fact. I found $[\alpha]_D^{20} = -12.23^{\circ}$ (calculated on the basis of $C_6H_{12}O_7$) for the pure crystalline acid, melting at 140 – 141° , in a 4% aqueous solution. Schnelle and Tollens¹ found that the specific rotation of free *d*-galactonic acid, on liberation from its calcium salt by hydrochloric or oxalic acids, was -10.56° (calculated on the basis of $C_6H_{12}O_7$). Nef observed that the specific rotation of a 4% aqueous solution of a similarly liberated acid was -12.64° , six minutes after its preparation; this fell to -11.35° and rose again to -10.10° after standing for 10 and 22½ hrs. respectively, at ordinary temperature.

The specific rotation of aqueous solutions of ortho-bis-*d*-galactonic acid increase and reach a limit at about -50° , after standing about three weeks at ordinary temperatures, or in one hour at 100° (see below); this is due to a transformation of the acid mainly into the isomeric *d*-galactonic γ -lactone hydrate, melting at 66° , with $[\alpha]_D^{20} = -70.1^{\circ}$ (see below). Since, however, this lactone hydrate is also slightly acted upon by water, even at 20° , aqueous solutions of γ -lactone hydrate, or of ortho-bis acid, finally always contain a mixture of three substances in equilibrium, namely, 70 to 80% of γ -lactone hydrate, 30 to 20% of free acid, besides traces of the γ -lactone (see below).

1.0383 g. of ortho-bis-*d*-galactonic acid (corresponding to 0.9927 g. $C_6H_{12}O_7$) dissolved in 25.0781 g. H_2O , gave $[\alpha]_D^{20} = -12.23^{\circ}$, six minutes after solution ($\alpha = -0.94^{\circ}$ in a 2 dc. tube). The changes observed in the specific rotation of this solution on standing at ordinary temperatures follow:

TABLE VI.

Time after solution.	Observed angle.	$[\alpha]_D$ calculated on basis of $C_6H_{12}O_7$.
2 days 16 hrs.	-2.51°	-32.66°
3 days 19 hrs.	-2.85°	-37.08°
4 days 23 hrs.	-2.97°	-38.64°
5 days 22 hrs.	-3.16°	-41.12°
9 days 17 hrs.	-3.36°	-43.71°
10 days 17 hrs.	-3.46°	-45.02°
17 days 17 hrs.	-3.90°	-50.75°

Another observation on the specific rotation of a preparation of ortho-bis-*d*-galactonic acid, which had been kept one year, gave $[\alpha]_D^{20} = -13.32^{\circ}$

¹ *Ann.*, 271, 85 (1892).

(calculated on the basis of $C_6H_{12}O_7$) i. e., 1.6143 g. *ortho-bis-d-galactonic* acid (corresponding to 1.544 g. $C_6H_{12}O_7$) dissolved in 36.1823 g. H_2O gave $\alpha = -1.10^\circ$ in a 2 dc. tube fourteen minutes after solution. Subsequent changes in the optical activity of this solution are recorded in this table:

TABLE VII.

Time after solution.	Observed angle.	$[\alpha]_D$ calculated on the basis of $C_6H_{12}O_7$.
2 hrs. 25 min.	-0.95°	-11.50°
3 hrs. 25 min.	-0.89°	-10.78°
5 hrs. 40 min.	-0.89°	-10.78°
7 hrs. 25 min.	-0.89°	-10.78°
11 hrs. 20 min.	-0.97°	-11.75°
1 day	-1.22°	-14.78°
2 days	-1.53°	-18.53°
3 days 8 hrs.	-1.85°	-22.41°
18 days	-3.76°	-45.54°

The slight drop at first observed in the specific rotation of an aqueous solution of *ortho-bis-d-galactonic* acid (from -11.50° to -10.78°) possibly indicates the presence of a plus-rotating β -lactone, which is very unstable in aqueous solution (see below). Similar changes were invariably noticed in the case of freshly prepared aqueous solutions of *d-galactonic* acid, when set free from its salts by acids. Ten grams of calcium *d-galactonate* ($Ca(C_6H_{11}O_7)_2 \cdot 4H_2O$ by analysis) for example were dissolved in 150 cc. H_2O and treated with 2.51 g. oxalic acid in water at 60° . After shaking a few seconds, the solution was cooled in one-half minute to 20° and filtered from calcium oxalate. The filtrate (containing by calculation 7.81 g. free *d-galactonic* acid, $C_6H_{12}O_7$) was made up to 250 cc. with water and gave $[\alpha]_D^{20} = -7.68^\circ$ one hour after precipitation of the calcium oxalate ($\alpha = -0.48^\circ$ in a 2 dc. tube). The following table gives the subsequent changes in the optical activity of this solution, kept at ordinary temperatures:

TABLE VIII.

Time after precipitation.	Observed angle.	$[\alpha]_D$ calculated on the basis of $C_6H_{12}O_7$.
3 hrs. 40 min.	-0.61°	-9.76°
22 hrs. 15 min.	-1.33°	-21.29°
1 day 22 hrs. 40 min.	-1.90°	-30.40°
4 days 7 hrs.	-2.72°	-43.52°
19 days 6 hrs.	-3.20°	-51.20°
23 days 2 hrs.	-3.22°	-51.52°

An aqueous solution of 1.0803 g. *ortho-bis-d-galactonic* acid (corresponding to 1.033 g. $C_6H_{12}O_7$), dissolved in 26.2848 g. H_2O , heated for one hour on a boiling water bath and cooled quickly to 20° , gave $\alpha = -1.85^\circ$ in a 1 dc. tube fifteen minutes after cooling; whence $[\alpha]_D^{20} = -48.51$ when calculated on the basis of lactone hydrate, $C_6H_{10}O_6 \cdot H_2O$. The

following facts: (1) the specific rotation of the solution on standing at room temperature for 14 days shows a notable rise in specific rotation and a subsequent fall back to -49.02° .

Time after cooling.	Observed angle.	$[\alpha]_D$ calculated on the basis of $C_6H_{10}O_7$.
2 hrs. 45 min.	-2.05°	-53.74°
20 hrs.	-2.10°	-55.05°
4 days	-2.05°	-53.74°
14 days	-1.90°	-49.82°

***d*-Galactonic γ -Lactone and Its Monohydrate.**—Schnelle and Tollens¹ were the first to obtain crystallized *d*-galactonic γ -lactone hydrate, $C_6H_{10}O_6 \cdot H_2O$, but they did not assign to it a structural formula. They gave the melting point, 66° , and found $[\alpha]_D^{20} = -65.6^\circ$ five minutes after solution. According to later observations by Clowes and Tollens,² a preparation, crystallized from acetone, with the same melting point, 66° , gave $[\alpha]_D^{20} = -67.9^\circ$. After driving off water from the hydrate by a stream of warm air, a preparation of γ -lactone, still contaminated with hydrate, was obtained by them in the form of needles melting at 90° with $[\alpha]_D^{20} = -72.1^\circ$. A preparation, melting at 100° , obtained by Hlasiwetz and Barth³ as early as 1862, also contained some unchanged hydrate, since *d*-galactonic γ -lactone is a very hygroscopic substance. Furthermore, it is obvious that the low specific rotations, obtained by Tollens and his co-laborers for the γ -lactone and its hydrate, were due to the presence of a small amount of ortho-bis-*d*-galactonic acid, since it is difficult to convert this substance completely into the γ -lactone. This can only be done, as Nef has repeatedly observed, by prolonged heating of residues at 20 mm. pressure in a distilling flask in a bath at 100° . By operating in this way he has, for example, repeatedly converted calcium *d*-galactonate, by treatment with oxalic acid, etc., to the extent of over 90% of the theory into pure *d*-galactonic γ -lactone, *i. e.*, by subsequently crystallizing the residual gums from *absolute* alcohol. It was, however, always necessary to re-heat the gums left in the alcoholic filtrates at 100° and under 20 mm. pressure; and in fact at least three or four such operations were necessary in order to obtain a ninety per cent. yield of γ -lactone. Prepared⁴ in this way, the γ -lactone crystallizes in needles, which melt between 108° and 111° and always give a specific rotation in the neighborhood of -77° , or of -70° , if calculated on the basis of γ -lactone hydrate, which is ob-

¹ *Ann.*, 271, 81 (1892).

² *Ibid.*, 310, 166 (1900).

³ *Ibid.*, 122, 96 (1862).

⁴ It is clear that the preparation of *d*-galactonic γ -lactone recently described by Ruff and Franz, *Ber.*, 35, 948 (1902), possessing $[\alpha]_D^{20} = -77.61^\circ$, must be identical with my product; the high melting point given, 135° , is probably due to a typographical error.

vously the only natural basis (see below), since the latter substance is practically the only one present in aqueous solutions at 20°.

The best way of obtaining a pure preparation of *d*-galactonic γ -lactone hydrate is to place the powdered γ -lactone and the calculated amount of water side by side in dishes in a closed vessel; the water is completely absorbed after two days' standing, and the resulting addition product is thereupon crystallized from ethyl acetate (see below).

The following further experiments with *d*-galactonic γ -lactone, as well as with γ -lactone hydrate, are of especial interest since they confirm in a very decisive way many of the preceding statements.

The above mentioned aqueous, and aqueous-alcoholic, mother liquors, from which 17.48 g. and 4.17 g. pure ortho-bis-*d*-galactonic acid had separated out by crystallization (see footnote, p. 364), were now freed from alcohol and water by distillation at reduced pressure and the residue, about 50 g. in 500 cc. H₂O, was now heated at 40° for 25 hrs. The water was again removed by distillation at 20 mm. pressure with the surrounding bath at 40°, until no more moisture condensed in the neck of the flask. The residual gum, 49.2 g., dissolved in cold water and made up to 500 cc., gave $[\alpha]_D^{20} = -47.49^\circ$ ($\alpha = -9.34^\circ$ in a 2 dc. tube; $c = 9.84$). The water was now again removed by distillation at 20 mm. pressure with the bath at 40°. The residual gum, on digestion at 40° with 200 cc. absolute alcohol, left 5.15 g. crystalline material undissolved, which melted from 113° to 119°, and was insoluble in warm absolute alcohol. The filtrate, freed from alcohol by distillation at reduced pressure, gave a residue which was heated at 60° until bubbles ceased to appear in the melt. This gum was soon transformed on standing into a crystalline mass which, when carefully broken loose by a rod and removed from the flask with 25 cc. absolute alcohol, yielded 29.6 g. air-dry crude γ -lactone hydrate melting from 65° to 70° with $[\alpha]_D^{20} = -55.83^\circ$ (calculated on the basis of C₆H₁₂O₇). A considerable portion of this, 19.8 g., when dissolved in 50 cc. of warm absolute alcohol, gave 8.07 g. mixed crystals melting from 66° to 85°; these, after drying three days over H₂SO₄ *in vacuo*, weighed 7.77 g., melted from 108° to 111°, and consisted therefore of practically pure γ -lactone.

Four grams of the finely powdered *d*-galactonic γ -lactone (melting from 108° to 111°) and the theoretical amount of water, 0.405 g., were placed side by side in dishes in an air-tight vessel. The water disappeared within two days; and the solid now weighed 4.44 g. and melted between 65° and 70°, but, after standing for two days over H₂SO₄ *in vacuo*, again lost the combined water with a simultaneous rise in melting point up to 105° to 110°. The γ -lactone had, therefore, been transformed into the hydrate and again recovered unchanged. It is obvious from these data that the *d*-galactonic γ -lactone is a very hygroscopic substance, which

can, therefore, be obtained from solvents containing no water; this explains why the melting point is found usually to range from 108° to 111° .

d-Galactonic γ -lactone is soluble in about 200 parts of boiling ethyl acetate and separates therefrom on standing in opaque needles. The γ -lactone hydrate crystallizes from this solvent in large transparent prisms.

1.48 g. mixed crystals of *d*-galactonic γ -lactone and hydrate were dissolved in 400 cc. boiling ethyl acetate; this, concentrated to 200 cc., yielded on standing 0.65 g. needles, melting from 90° to 105° ; these, dried over H_2SO_4 in *vacuo* for three days, melted at $109\text{--}111^{\circ}$ with $[\alpha]_D^{20} = -76.97^{\circ}$ (calculated on the basis of $\text{C}_6\text{H}_{10}\text{O}_6$) consisting therefore of pure γ -lactone.

2.58 g. mixed crystals of γ -lactone and hydrate were dissolved in 350 cc. boiling ethyl acetate; this solution on standing yielded 1.5 g. large transparent prisms, melting at $65\text{--}67.5^{\circ}$ (air-dried) with $[\alpha]_D^{20} = -70.1^{\circ}$ (calculated on the basis of $\text{C}_6\text{H}_{10}\text{O}_6 \cdot \text{H}_2\text{O}$). This was pure *d*-galactonic γ -lactone hydrate. There must, therefore, be enough water in ordinary ethyl acetate to transform the γ -lactone into the hydrate. In a special experiment 0.5 g. *d*-galactonic γ -lactone, melting from 100° to 110° ; dissolved in 75 cc. boiling ethyl acetate, gave, on concentration to two-thirds the original volume, a considerable amount of gum on standing; this slowly and completely became transformed into large transparent prisms of γ -lactone hydrate melting from $64^{\circ}\text{--}67^{\circ}$.

Finally there are appended here data (physical, analytical, etc.) which were obtained with *d*-galactonic γ -lactone and its hydrate.

***d*-Galactonic γ -lactone.**—0.5721 g. substance, heated 10 min. on a boiling water bath with an excess of 0.1 *N* KOH, cooled and titrated back with 0.1 *N* H_2SO_4 , etc., used 32.01 cc. 0.1 *N* KOH (phenolphthalein) for neutralization instead of 32.12 cc. calculated for $\text{C}_6\text{H}_{10}\text{O}_6$.

A molecular weight determination with 0.5602 g. substance in boiling absolute alcohol using McCoy's apparatus (*Loc. cit.*) gave as the average molecular weight 192.3 instead of 178 calculated for $\text{C}_6\text{H}_{10}\text{O}_6$.

Vol. of solution, cc.	24.3	29.0	31.3	33.0	
Rise in B. P.	0.184°	0.156°	0.148°	0.137°	
Mol. wt. found.	195	193	188	193	Av. 192.3

The specific rotation of pure γ -lactone was found to be -76.97° , or better -69.88° , when calculated on the basis of γ -lactone hydrate, since obviously this is practically the only substance present at first in a fresh aqueous solution, *i. e.*, 0.3464 g. substance and 9.0443 g. H_2O gave $\alpha = -2.87^{\circ}$ in a 1 dc. tube eight minutes after solution. The solution then underwent the following changes on standing at ordinary temperatures:

TABLE IX.

Time after solution.	Observed angle.	$[\alpha]_D$ specific rotation for lactone hydrate.
20 hrs.	-2.79°	-67.92°
4 days $4\frac{1}{2}$ hrs.	-2.73°	-66.45°
9 days 1 hr.	-2.52°	-61.33°
13 days 19 hrs.	-2.41°	-58.65°
14 days 19 hrs.	-2.37°	-57.67°
21 days 19 hrs.	-2.25°	-54.77°
23 days 18 hrs.	-2.19°	-53.30°
28 days 16 hrs.	-2.18°	-53.07°
35 days 1 hr.	-2.03°	-49.41°
44 days 19 hrs.	-1.98°	-48.20°

d-Galactonic γ -Lactone Hydrate.—0.6450 g. required 32.72 cc. 0.1 *N* KOH for neutralization by the usual method (see above) instead of 32.91 cc. calculated from $C_6H_{10}O_6 \cdot H_2O$.

The specific solution of the γ -lactone hydrate was found to be -70.1° , i. e., 0.3906 g. substance and 9.7905 g. H_2O gave $\alpha = -2.72^\circ$ in a 1 dc. tube ten minutes after solution. The solution then underwent the following changes at ordinary temperatures:

TABLE X.

Time after solution.	Observed angle.	$[\alpha]_D$.
$17\frac{3}{4}$ hrs.	-2.64°	-68.07°
2 days $17\frac{1}{2}$ hrs.	-2.63°	-67.77°
4 days 20 hrs.	-2.60°	-67.02°
7 days $1\frac{1}{2}$ hrs.	-2.47°	-63.67°
12 days 1 hr.	-2.32°	-59.80°
16 days 20 hrs.	-2.25°	-58.00°
24 days $20\frac{1}{2}$ hrs.	-2.20°	-56.70°
26 days 18 hrs.	-2.14°	-55.15°
31 days 18 hrs.	-2.08°	-53.68°
38 days 1 hr.	-1.98°	-51.10°
47 days 19 hrs.	-1.89°	-48.77°

When *d*-galactonic γ -lactone is heated in a boiling water bath in 4% aqueous solution, equilibrium is quickly reached with the specific rotation between -58° and -61° , if the calculation is made on the only natural basis of $C_6H_{12}O_7$, which is the empirical formula of *d*-galactonic γ -lactone hydrate, as well as of free *d*-galactonic acid. This is decidedly higher than the specific rotations, about -48.5° (see above), finally reached by aqueous solutions of ortho-bis-*d*-galactonic acid, as well as of *d*-galactonic γ -lactone and its hydrate, and proves, as in all other instances (cf. *d*-mannonic and *d*-gluconic series), that more lactone (or lactone hydrate) is present in aqueous solution at higher temperatures. Thus, (A) a solution of 0.5363 g. *d*-galactonic γ -lactone in 11.7732 g. H_2O , heated for one hour on a boiling water bath and cooled quickly, gave $[\alpha]_D^{20} = -60.42^\circ$ i. e., $\alpha = -2.93^\circ$ in a 1 dc. tube. (B) A second experiment with 0.5769

g. γ -lactone in 13.4041 g. H_2O , heated for five hours on a boiling water bath and cooled quickly gave $[\alpha]_D^{20} = -58.79^\circ$, *i. e.*, $\alpha = -2.75^\circ$ in a 1 dc. tube; curiously enough the specific rotation rose after 16 hours' standing at room temperatures to -59.87° . (C) A third experiment with 0.5035 g. γ -lactone in 11.9932 g. H_2O , heated on a boiling water bath for seven hours and cooled quickly, gave $[\alpha]_D^{20} = -59.54^\circ$, *i. e.*, $\alpha = -2.67^\circ$ in a 1 dc. tube. Here again a curious rise and subsequent fall in specific rotation were observed on standing at ordinary temperatures.

Time after first reading.	Observed angle.	$[\alpha]_D$.
19 hrs.	-2.77°	-61.77°
6 days	-2.54°	-56.63°

It is clear from the data presented that aqueous solutions of ortho-bis-*d*-galactonic acid, or of *d*-galactonic γ -lactone or its hydrate, finally come to an equilibrium at 20° with $[\alpha]_D^{20} = -48.5^\circ$; at 100° , on the other hand, equilibrium is quickly reached with $[\alpha]_D^{20} = -60^\circ$. Such solutions contain 17 to 37% of free *d*-galactonic acid and 83 to 63% of *d*-galactonic γ -lactone hydrate (besides traces of γ -lactone) according to the temperature (between 20° and 100°) at which equilibrium occurs.

One might also draw the conclusion from the slight fluctuations at first noticed in the specific rotation of ortho-bis-*d*-galactonic acid, or of free *d*-galactonic acid when set free from its salts, as well as the curious fluctuations in specific rotation noticed after aqueous solutions of ortho-bis-*d*-galactonic acid and of *d*-galactonic γ -lactone have been heated at 100° and quickly cooled, that a faintly dextrorotatory *d*-galactonic β -lactone also exists in these solutions. All attempts, however, to isolate such a β -lactone, or even an ester of *d*-galactonic acid, were entirely fruitless.

I desire to express my gratitude to Dr. Nef for his painstaking instruction and constant aid in this work.

CHICAGO, ILL.

SYNTHESES IN THE DIPHENYLMETHANE SERIES.

BY LAMBERT THORP AND E. A. WILDMAN.¹

Received December 11, 1914.

The work presented in this paper was undertaken with the idea of attempting to effect a synthesis of the hydrocarbon, fluorene, through the action of metals upon 2,2'-dibromodiphenylmethane. This latter substance was prepared by the elimination of the amino groups from 3,3'-diamino-6,6'-dibromodiphenylmethane, a compound which, in turn, had

¹ The work described in this article formed part of a thesis submitted for the degree of Master of Science to the graduate school of the University of Illinois by E. A. Wildman.

been obtained by acetylation and subsequent bromination of 3,3'-diaminodiphenylmethane.

In marked contrast to the usual ease with which, under the influence of sodium or other metals, ring formation occurs in the case of organic compounds halogenated in the 1,5-position, is the behavior of 2,2'-dibromodiphenylmethane under similar circumstances. Although sodium was allowed to act upon the dibromodiphenylmethane, both in anhydrous ether solution and in boiling xylene, and although the substance was subjected to the action of other metals, such as copper in the form of "Naturkupfer," and magnesium at temperatures up to 260°, the bromo-compound was in all cases recovered almost entirely unchanged, the only observed effect of the treatment being a slight reduction to diphenylmethane.

An interesting case of steric hindrance is observable in the behavior of hydroxylamine or of semicarbazine towards 2,2'-dibromobenzophenone, obtained by the oxidation of 2,2'-dibromodiphenylmethane. In the case of the former of these reagents several hours' boiling of the solution was insufficient to involve the ketone in reaction; and after being exposed to the action of semicarbazine for a month the ketone was recovered unchanged from the solution.

Experimental.

***m*-Nitrobenzyl Alcohol.**—In general the method of Becker¹ was followed, wherein *m*-nitrobenzaldehyde was subjected to the action of potassium hydroxide, in accordance with the well-known reaction of Cannizzaro. It was found advantageous, however, to saturate the alkaline solution with carbon dioxide before extracting the alcohol with ether. Under these circumstances the yield amounts to 92% of the theoretical.

3,3'-Dinitrodiphenylmethane.—This substance was first described by Gattermann and Rüdts² who prepared it by the condensation of *m*-nitrobenzylalcohol with nitrobenzene in the presence of sulfuric acid. In the same year, M. Schöpf³ obtained the compound through the action of formaldehyde upon nitrobenzene in sulfuric acid solution. Baeyer,⁴ employing, with slight modifications, the method of Gattermann and Rüdts, prepared the substance in 25% yield, the amount of tarry material formed at the same time being considerable.

At first, in our attempts to improve the yield by changing the conditions of condensation, 10 g. of *m*-nitrobenzylalcohol and 30 g. of nitrobenzene were dissolved in 200 cc. of concentrated sulfuric acid, and the solution allowed to remain at room temperature for 72 hrs. After the reaction mixture had been poured upon cracked ice it was observed that the amount

¹ *Ber.*, 15, 2090 (1882).

² *Ibid.*, 27, 2295 (1894).

³ *Ibid.*, 27, 2321 (1894).

⁴ *Ann.*, 354, 192 (1907).

of tarry material formed was negligible; hence it was unnecessary to purify the product by means of acetone, as recommended by Baeyer. The yield amounted to 20% of the theoretical.

Again, upon allowing the mixture to stand at room temperature for eleven days, the quantity of tar formed was very small, while the yield was increased to 25%.

After the solution of nitrobenzyl alcohol and nitrobenzene had remained on the water bath at a temperature of 95–97° for six hrs., the yield amounted to only 14%, while a similar treatment for 18 hrs. gave a 20% yield. Finally, after 48 hrs. at a temperature of 95–97°, the yield increased to 30%, the amount of tarry material being very slight. Accordingly, these conditions were adopted for the preparation of 3,3'-dinitrodiphenylmethane.

3,3'-Diaminodiphenylmethane.—This base was first prepared by M. Schöpf¹ from the corresponding dinitro-compound by reduction with stannous chloride. The yield, however, was poor. Better results were obtained with metallic iron and acetic acid.

Fourteen grams of 3,3'-dinitrodiphenylmethane were mixed in a porcelain dish with 30 g. of iron, in the form of powder, and 50 cc. of water. Two cubic centimeters of glacial acetic acid were added, and the mixture was then heated on the water bath, with constant stirring, until the reaction was apparently at an end. After about 2 hrs. further heating the greater part of the water had evaporated. The base was extracted with ether, the ethereal solution dried over potassium hydroxide, and the ether distilled. The product, which was obtained as a viscous oil, was immediately converted into its acetyl derivative.

3,3'-Diacetylaminodiphenylmethane.—The diamine, obtained as described above, was dissolved in 20 cc. of glacial acetic acid, and 15 cc. of acetic anhydride were added to the solution. Heat was evolved, and the reaction was brought to completion by warming the solution to its boiling point. The acetyl derivative, which separated in crystalline condition upon pouring the reaction mixture into cold water, was filtered with the aid of suction, and recrystallized from dilute alcohol. The yield was 13 g. or 83% of the theoretical, based upon the nitro compound.

3,3'-Diacetylaminodiphenylmethane crystallizes in the form of colorless leaflets, and has a melting point of 193°. It is readily soluble in alcohol or glacial acetic acid; slightly soluble in ether, benzene or ligroin; very slightly soluble in water.

0.2897 g. substance: 25.9 cc. N₂ (26°, 745 mm., over KOH).

Calc. for C₁₇H₁₆O₂N₂: N, 9.82; found: 9.90%.

3,3'-Diacetylamino-6,6'-dibromodiphenylmethane.—Twenty grams of 3,3'-diacetylaminodiphenylmethane were dissolved in 500 cc. of glacial

¹ Ber., 27, 2322 (1894).

acetic acid, and to the solution, maintained at a temperature of 50° and constantly stirred, 17 g. of bromine were gradually added. Fumes of hydrogen bromide were evolved. The mixture was allowed to stand for a short time, and then poured into four times its volume of cold water. The product was filtered at the pump, and washed with cold water. Yield, 26 g., or 84% of the theoretical.

3,3'-Diacetyl-amino-6,6'-dibromodiphenylmethane crystallizes in the form of small, colorless plates from glacial acetic acid, in which it is fairly soluble, or from alcohol, in which it is only slightly soluble. It is very difficultly soluble in ether, benzene, ligroin or carbon tetrachloride. The melting point is 284°.

0.2987 g. subs. required 27.1 cc. 0.05 *N* AgNO₃; 0.2964 g. gave 17.0 cc. N₂ (25°, 753 mm. over KOH).

Calc. for C₁₇H₁₆O₂N₂Br₂: Br, 36.34; N, 6.36; found: Br, 36.25%; N, 6.40%.

3,3'-Diamino-6,6'-dibromodiphenylmethane.—Sixty grams of the diacetyl compound and 250 cc. of alcohol were placed in a flask, provided with a reflux condenser. The mixture was heated to boiling, and then 200 cc. of hydrochloric acid (sp. gr. 1.19) were added gradually. After half an hour's heating saponification was complete, and the solution entirely clear. Soon the hydrochloride of the base began to crystallize out in the form of fine, colorless needles. At this point boiling was discontinued and the solution allowed to cool. The product was filtered off, and washed with alcohol, the greater part of the impurities remaining in the mother liquor. The latter was evaporated almost to dryness on the water bath, ammonia added, and the base extracted with ether. From the ethereal solution the almost pure salt was precipitated by means of hydrogen chloride.

When an aqueous solution of the hydrochloride is treated with ammonia the base is precipitated as an oil which soon solidifies to a mass of crystals, easily soluble in ether, alcohol or glacial acetic acid. After several recrystallizations from alcohol the substance showed a melting point of 114°. The base is rather unstable as, upon exposure to the air, it quickly turns brown.

On account of the instability of the free base it was decided to analyze the sulfate, since this salt was found to be only slightly soluble in cold water, and could easily be purified by recrystallization from this medium.

0.2983 g. subs. gave 14.1 cc. N₂ (20°, 746 mm.); 0.4602 g. subs. required 33.2 cc. 0.05 *N* AgNO₃.

Calc. for C₁₃H₁₂N₂Br₂.(H₂SO₄)₂: N, 5.07; Br, 29.02; found: N, 5.27; Br, 28.82.

A sample of the hydrochloride was titrated against standard potassium hydroxide solution, with phenolphthalein as indicator.

Calc. for C₁₃H₁₂N₂Br₂.2HCl: HCl, 17.40; found: 17.20.

2,2'-Dibromodiphenylmethane.—This substance was prepared by replacing in 3,3'-diamino-6,6'-dibromodiphenylmethane the amino groups

with hydrogen. Several unsuccessful attempts were made to eliminate the amino groups before a satisfactory method was found. Thus, neither the diazotization of the hydrochloride of the base by means of amyl nitrite in alcoholic solution, nor the reduction of the diazonium compound with sodium stannite, nor the oxidation of the corresponding hydrazine with copper sulfate or with potassium chromate led to satisfactory results. The procedure outlined below furnishes, however, a fairly good yield of 2,2'-dibromodiphenylmethane.

Ten grams of the hydrochloride of the base were made into a paste with 30 cc. of water and 10 cc. of hydrochloric acid (1.19). The mixture was maintained at a temperature of 0° while a cold, saturated solution of sodium nitrite was slowly added until a test with starch-iodide paper indicated free nitrous acid, the presence of a slight excess of which was found desirable since the salt diazotized somewhat slowly. When the mixture had become entirely homogeneous it was poured into one liter of boiling alcohol. A brisk evolution of nitrogen followed. The alcohol was distilled, and the remaining light brown oil taken up with ether. After the ethereal solution had been dried over calcium chloride, and the solvent removed, the residue was distilled under a pressure of 45 mm. The yield was 6.5 g. of a pale yellow, heavy liquid which came over between 220 and 245°. In an attempt to further purify the substance by distillation under 5 mm. pressure, a nearly colorless fraction was obtained between 212 and 218°. It seemed to be a mixture, however, and this supposition was confirmed by analysis.

0.2536 and 0.1403 g. subs. required 29.4 and 16.3 cc. 0.05 N AgNO₃.

Calc. for C₁₃H₁₀Br₂: Br, 49.04; found: 46.32 and 46.42.

Since the bromine content was low it was supposed that the impurity might be the ethoxy derivative which might have been formed as a by-product in the decomposition of the diazonium salt by the alcohol. Accordingly, 12 g. of the distillate were shaken with 40 cc. of concentrated sulfuric acid, and the insoluble portion which rose to the surface of the acid was separated, and distilled under 40 mm. A colorless liquid, boiling constantly at 234–235° was collected.

0.1419 g. subs. required 17.2 cc. 0.05 N AgNO₃.

Calc. for C₁₃H₁₀Br₂: Br, 49.04; found: 48.44.

The indices of refraction and dispersion were determined by means of an Abbé refractometer.

$n_D(20^\circ) = 1.6300$

$n_F - n_C(20^\circ) = 0.0213$

Specific gravity: $D_4^{20} = 1.6197$.

Action of Metals upon 2,2'-Dibromodiphenylmethane.—A solution of 10 g. of 2,2'-dibromodiphenylmethane in 150 cc. of anhydrous ether was treated with a slight excess of sodium wire, and the mixture allowed to

remain at room temperature for 24 hrs. After filtration and distillation of the ether, the original bromo compound was recovered unchanged.

Two grams of 2,2'-dibromodiphenylmethane and an excess of sodium wire were added to 50 cc. of anhydrous xylene, and the solution maintained at the boiling point for 6 hrs. Except for a slight reduction to diphenylmethane, due probably to a trace of moisture, there was no apparent action.

Two grams of the bromo compound, together with 2 g. of copper bronze, were heated to a temperature of 260° for several hours, according to the method of Ullmann. The original compound was recovered unchanged.

In the same manner, and with similar results, 2 g. of 2,2'-dibromodiphenylmethane with 2 g. of powdered magnesium and a trace of iodine were maintained at a temperature of 260° for one hour.

2,2'-Dibromodiphenylketone.—Five grams of 2,2'-dibromodiphenylmethane were dissolved in 50 cc. of glacial acetic acid. Ten grams of chromic anhydride in saturated aqueous solution were added, and the mixture heated on the water bath for six hours. The solution was then poured into ten times its volume of water, and the ketone extracted with ether. The acetic acid was removed from the ethereal extract by shaking with dilute potassium hydroxide solution. After drying over anhydrous sodium sulfate, and distillation of the ether, a colorless oil remained. A few cubic centimeters of alcohol were added to the oil, and the mixture stirred, whereupon the ketone was obtained as a crystalline mass. From its alcoholic solution the substance separates in the form of beautiful, hexagonal plates, melting at 86°.

2,2'-Dibromobenzophenone is insoluble in water; readily soluble in ether, acetone, chloroform, carbon tetrachloride, hot glacial acetic acid or hot alcohol.

0.3067 g. subs. required 35.6 cc. 0.05 *N* AgNO₃.

Calc. for C₁₃H₈OBr₂: Br, 47.02; found: 46.38.

In an attempt to prepare the oxime, equivalent quantities of ketone, hydroxylamine sulfate and potassium hydroxide in dilute alcoholic solution were heated for eight hours under a reflux condenser. Water was then added, and the mixture extracted with ether. From the ethereal solution the ketone was recovered unchanged.

In the same way, attempts to prepare the semicarbazone yielded negative results, even though the solution was allowed to stand for a month.

Oximes of analogously constituted ketones have never been prepared, owing probably to steric hindrance. Under very energetic treatment a Beckmann rearrangement may take place. If one of the substituents in the ortho position is a halogen atom another type of reaction may occur under the influence of alkali: formation of a five-membered heterocyclic compound of the isoxazole type.

RESEARCHES ON PYRIMIDINES. LXXIV. SYNTHESIS OF
4-PHENYLCYTOSINE.

BY TREAT B. JOHNSON AND E. HEATON HEMINGWAY.

Received December 16, 1914.

Introduction.

In a previous publication from this laboratory entitled "The Isomerism of 4-Phenylisocytosine," Johnson and Hill¹ have given a description of four isomeric modifications of this aminopyrimidine. Each modification was characterized by its crystalline habit and also by the property of crystallizing in an anhydrous condition. All four isomers, however, combined with hydrochloric acid forming the same monohydrochloride which contained one molecule of water of crystallization. Nothing definite regarding the constitution of these four isomers was contributed. In continuing the study of this question of pyrimidine-isomerism it became of special interest to determine first whether other types of pyrimidines, besides those containing the guanidine grouping, would likewise undergo metamerie changes. In other words, is this simply a special case of physical isomerism or a type of pyrimidine-stereoisomerism which theoretically might be expected to occur in other classes of pyrimidines. As a typical representative of another type of aminopyrimidines we, therefore, selected for investigation a urea combination; *viz.*, 4-phenylcytosine (II), whose relationship to 4-phenylisocytosine (I) is apparent by inspection of the two following formulas. Formula I represents a

guanidine compound while phenylcytosine (II) contains the amidine grouping $\text{H}_2\text{N}-\overset{|}{\text{C}}=\text{N}-$. A description of the synthesis and properties of this pyrimidine (II) is now given in this paper.

Phenylisocytosine (I) is prepared by the interaction of guanidine carbonate with ethyl benzoylacetate in alcohol solution. Jaeger² and Warmington³ independently prepared the pyrimidine in this manner and their observation was confirmed by Johnson and Hill.⁴ The latter also observed that isomeric modifications of this pyrimidine are obtained by condensing guanidine with the β -ketone ester in the presence of sodium ethylate.

¹ THIS JOURNAL, 36, 1202 (1914).² Ann., 262, 373 (1890).³ J. prakt. Chem., [2] 47, 214 (1893).⁴ Loc. cit.

By the condensation of thiourea with ethylbenzoylacetate, 2-thio-4-phenyluracil (III) is easily obtained. Warmington¹ accomplished this synthesis by heating dry thiourea or ammonium thiocyanate with the β -ketone ester at 170–180°, and obtained a yield of pyrimidine corresponding to about 30% of the theoretical. Attempts to bring about this condensation under other conditions were unsuccessful. For example, Warmington¹ writes as follows: "Weder durch die Einwirkung von Chlorwasserstoffsäure, Bromwasserstoffsäure oder Iodwasserstoffsäure oder von Natriumäthylat bei Gegenwart von Alkohol, noch durch die Verwendung von Eisessig als Lösungsmittel und nachheriges Einleiten von Salzsäuregas der Versetzen mit concentrirter Schwefelsäure in geringer Menge oder mit Essigsäureanhydrid gelang es, Benzoylessigester mit Harnstoff oder Thioharnstoff zu condensiren." On repeating Warmington's work we have not been able to confirm all his conclusions.

We now find that 2-thio-4-phenyluracil (III) can easily be prepared by digesting thiourea with ethyl benzoylacetate in alcohol solution and in the presence of sodium ethylate. In fact, the reaction is so smooth that a yield of the pyrimidine is obtained, which corresponds to over 73% of the theoretical. There is far less secondary decomposition than when the thiourea is heated directly with the β -ketone ester as recommended by Warmington.

2-Thio-4-phenyluracil (III) undergoes alkylation smoothly when its sodium salt is digested in alcohol solution with ethyl bromide, giving the corresponding mercaptopyrimidine, namely, 2-ethylmercapto-4-phenyl-6-oxypyrimidine (V). The corresponding 2-methylmercapto compound has been described by Wheeler and Merriam.² When digested with hydrochloric acid, mercaptan is evolved and the mercaptopyrimidine (V) is converted quantitatively into 4-phenyluracil³ (IV). 4-Phenyluracil is also quantitatively formed by direct desulfurization of 2-thio-4-phenyluracil (III). This is easily accomplished by digestion of the thiopyrimidine with chloroacetic acid.

When 2-ethylmercapto-4-phenyl-6-oxypyrimidine (V) is warmed with phosphorus oxychloride they interact smoothly, forming the halogen derivative 2-ethylmercapto-4-phenyl-6-chloropyrimidine (VI). This chloropyrimidine can be distilled under reduced pressure without decomposition. If heated with strong alcoholic ammonia the halogen is removed and 2-ethylmercapto-4-phenyl-6-aminopyrimidine (VII) is the product of the reaction. This aminopyrimidine (VII) undergoes a normal hydrolysis when digested with hydrobromic acid solution, giving ethylmercaptan and the hydrobromic acid salt of 4-phenylcytosine. The yield of this

¹ *Loc. cit.*

² *Am. Chem. J.*, **29**, 478 (1903).

³ Warmington, *Loc. cit.*

salt is nearly quantitative. The free base (II) is easily obtained by decomposing this salt with the required amount of ammonia or sodium hydroxide. These various transformations are expressed by the following structural formulas:

While cytosine¹ crystallizes with one molecule of water, it is of interest to note that this is not a general property which is characteristic of its carbon-substituted derivatives. In fact, only one of the thirteen carbon-substitution products, thus far described in papers from this laboratory, has crystallized in a hydrous condition; *viz.*, 5-aminocytosine.² We now find that phenylcytosine is another exception to the rule and likewise crystallizes with one molecule of water. Phenylcytosine is not characterized by such unique physical and chemical properties as was observed in the case of its isomer phenylisocytosine.³ It does, however, exist in two distinct modifications. Neither modification possesses any definite melting or decomposition point. They are, however, characterized by their individual crystalline habit. Both modifications are obtained by crystallization from alcohol and also undergo interconversion in the same solvent. The conditions under which these changes are produced are described in the experimental part of this paper. Both modifications combine with hydrochloric and hydrobromic acids respectively, giving the same salts.

Experimental Part.

The ethylbenzoylacetate, which was used in this work, was prepared according to the directions of Wahl and Doll.⁴

2-Thio-4-Phenyluracil (III).—This pyrimidine can easily be prepared according to the following procedure: Three and three-tenths grams of

¹ Wheeler and Johnson, *Am. Chem. J.*, **29**, 492 (1903).

² Johnson, Johns and Heyl, *Ibid.*, **36**, 160 (1906).

³ Johnson and Hill, *Loc. cit.*

⁴ *Bull. soc. chim.*, [41] **13**, 265 (1913).

metallic sodium are first dissolved in 45 cc. of absolute alcohol and 7 g. of thiourea dissolved in the solution. Thirteen and eight-tenths grams of ethyl benzoylacetate are then added and the mixture digested on the steam bath for several hours (10–12). The excess of alcohol is then evaporated by heating at 100° and the sodium salt of phenylthiouracil dissolved in the least possible quantity of cold water. This solution is then cooled and acidified with hydrochloric acid when the pyrimidine will separate in a crystalline condition. The yield obtained was 10.7 g., corresponding to about 73.3% of the theoretical. It crystallized from acetic acid in needles and melted at 259°.

Desulfurization of 2-Thio-4-phenyluracil by Digestion with Chloroacetic Acid.—Four grams of the thiopyrimidine and 4 g. of chloroacetic acid in 12 cc. of water were digested on a sand bath. The thiopyrimidine dissolved and after digesting for 2 hours 4-phenyluracil began to deposit from the hot solution. On cooling, the desulfurized pyrimidine separated completely and was purified by crystallization from alcohol. It deposited as prismatic crystals which melted at 270°.¹ The yield was practically quantitative.

2-Ethylmercapto-4-phenyl-6-oxypyrimidine (V).—This mercaptopyrimidine is easily prepared by digesting the sodium salt of 2-thio-4-phenyluracil in alcohol solution with the required amount of ethylbromide. After the reaction is complete the alcohol is then removed by evaporation and the mercaptopyrimidine separated from sodium bromide by trituration with cold water. The pyrimidine is insoluble in this solvent. It can be purified best by crystallization from absolute alcohol. It separates from this solvent in the form of needles which melt at 226°. The compound is insoluble in ether but soluble in benzene. The yield was 78% of the theoretical. The compound was dried for analysis by heating at 120°.

Calculated for $C_{12}H_{12}ON_2S$, $N = 12.06$; found, $N = 11.8$.

2-Ethylmercapto-4-phenyl-6-chloropyrimidine (VI).—Our method of preparing this halogenated pyrimidine was as follows: Twenty-two and five-tenths grams of the mercaptopyrimidine were placed in a dry flask and the latter connected with a reflux condenser. One hundred cc. of phosphorus oxychloride were then added through the condenser tube and the mixture heated on a steam bath. Hydrochloric acid was copiously evolved and the pyrimidine completely dissolved. After 5 hours' digestion the excess of phosphorus oxychloride was then removed by heating at 40–45° under diminished pressure and the residue poured into about 300 cc. of cold water. After thorough agitation to decompose any phosphorus halides present, the pyrimidine was then extracted with ether. The ether solution was washed with dilute sodium hydroxide solution and finally dried over anhydrous calcium chloride. After removal of the ether

¹ Wheeler and Merriam, *Am. Chem. J.*, 29, 490 (1903).

the pyrimidine was then purified by distillation under diminished pressure. It practically all distilled at 232° at 26.5 mm. pressure and the oil showed no signs of solidifying when cooled to -10° . The yield of purified product was 19.5 g. or 80.6% of the theoretical. In a second experiment we used 13 g. of the mercaptopyrimidine and obtained 9.45 g. of the chloropyrimidine boiling from $235-245^{\circ}$ at 30-40 mm. pressure.

Calculated for $C_{12}H_{11}N_2SCl$, $N = 11.18$; found, $N = 11.03$ and 11.10 .

The chloropyrimidine is converted quantitatively into 4-phenyluracil by hydrolysis with hydrochloric acid.

2-Ethylmercapto-4-phenyl-6-aminopyrimidine (VII).—This aminopyrimidine is formed by heating the above chloropyrimidine with strong alcoholic ammonia for two hours at $130-135^{\circ}$. On opening the bomb tube there was no pressure, but ammonium chloride was suspended in the solution. This was separated by filtration and the solution evaporated at 100° when the aminopyrimidine was obtained as an oil which solidified on cooling. The yield was 15.5 g. It was further purified by crystallization from 9.5% alcohol. It crystallized from this solvent in thin plates which melted at 120° to a clear oil. In a second experiment we obtained 6 g. of pure aminopyrimidine from 9.4 g. of the chloropyrimidine.

Calc. for $C_{12}H_{13}N_3S$, $N = 18.18$; found, $N = 18.01$ and 18.25 .

4-Phenylcytosine (II).—This pyrimidine was obtained in the form of its hydrobromic acid salt by hydrolysis of 2-ethylmercapto-4-phenyl-6-aminopyrimidine with hydrobromic acid. Eleven grams of the mercaptopyrimidine were dissolved in 75 cc. of hydrobromic acid and the mixture boiled on a sand bath for 6 hours when the evolution of mercaptan had ceased. The hydrobromide separated on cooling. After evaporating the excess of acid the salt was then purified by crystallization from water. It separated in the form of long needles which did not melt below 300° . The salt contained one molecule of water of crystallization which was determined by heating at 110° . Nitrogen determination on anhydrous salt.

Calc. for $C_{10}H_{10}ON_3Br \cdot H_2O$, $N = 15.67$, $H_2O = 6.29$; found, $N = 15.85$ and 15.51 , $H_2O = 6.20$.

In order to obtain the free pyrimidine base (4-phenylcytosine) this salt was dissolved in water and the hydrobromic acid neutralized by adding aqueous ammonia solution. The pyrimidine separated at once in a crystalline condition. This base is insoluble in cold ammonia but soluble in sodium hydroxide solution. The pyrimidine dissolved in boiling water and alcohol and crystallized from both solvents in the form of needles arranged in rosetts. They did not melt or decompose below 300° . When this base was first prepared (January, 1914), it was observed to crystallize only in the form of needles. This material was then bottled and not examined further until November, 1914. It had not changed in appearance during this time. On recrystallizing the pyrimidine from alco-

hol as before we observed, however, a remarkable difference in behavior. The compound dissolved without difficulty in boiling absolute alcohol, but, on cooling, needles did not deposit as previously observed. Instead, the pyrimidine separated in characteristic blocks of rhombohedral habit. If recrystallized from 95% alcohol a mixture of needles and blocks was obtained in which the blocks predominated. In fact it was almost impossible to obtain needles alone by crystallization from alcohol. The pyrimidine base was synthesized a second time in November, 1914, and purified according to our original method. The base behaved exactly as the original preparation. We could obtain at will, by crystallization from 95% alcohol, the needle and prism modifications. Although the pyrimidine was purified by crystallization from absolute and 95% alcohol it still contained one molecule of water of crystallization. So firmly was this bound in the molecule that it could not be expelled by heating at 100°. At 120° it was removed with difficulty. At the same time the pyrimidine apparently underwent a partial hydrolysis, which accounts for the low analytical values obtained for nitrogen.

Water determination:

Calc. for $C_{10}H_9N_3 \cdot H_2O$, $H_2O = 8.7$; found, $H_2O = 8.31$.

Nitrogen determinations in the anhydrous base:

Calc. for $C_{10}H_9ON_3$, $N = 22.4$; found, $N = 22.1, 21.91$ and 21.95 .

Hydrochloride, $C_{10}H_9ON_3 \cdot HCl \cdot H_2O$.—This salt is easily obtained by dissolving the pyrimidine base in dilute hydrochloric acid and then allowing the solution to crystallize. It separated in the form of long, colorless needles which melted at 274° with decomposition. The salt was dried for analysis over concentrated sulfuric acid.

Calc. for $C_{10}H_9ON_3 \cdot HCl \cdot H_2O$, $N = 17.44$; found, $N = 17.58$ and 17.49 .

The nitrate of 4-phenylcytosine is characterized by its property of crystallizing from water in two distinct forms. When it deposits from a hot, saturated aqueous solution it first separates in the form of needles. This form, however, is not permanent and as the solution cools the needles disappear and are replaced by characteristic prismatic crystals. The salt decomposes when heated above 245°.

NEW HAVEN, CONN.

RESEARCHES ON HYDANTOINS. XXX. STEREOISOMERIC MODIFICATIONS OF BENZALHYDANTOIN.

By TREAT B. JOHNSON AND JOSEPH S. BATES.

Received December 16, 1914.

Benzalhydantoin (II) was first prepared by Ruhemann and Cunningham¹ by heating ethyl phenylpropiolate with urea in alcohol solution and in the

¹ *J. Chem. Soc.*, 75, 958 (1899).

presence of sodium ethylate. They supposed the product of this reaction to be the ureide (I) and it was not until Ruhemann and Stapleton¹ later reinvestigated the reaction that it was shown that this conclusion was incorrect, and that the compound formed is really the hydantoin represented by Formula II. Thiourea and guanidine condense in an analogous manner, giving the corresponding cycles represented by Formulas III and IV, respectively.

No attention was paid further to this hydantoin (II) until 1911 when Wheeler and Hoffmann² found that the same compound is obtained smoothly by condensing hydantoin with benzaldehyde. They assigned to the compound the same melting point as observed by Ruhemann and his co-workers, namely, 220°. Since this work of Wheeler and Hoffmann the hydantoin has been prepared a great many times by their method and in large quantities, but in no case has it hitherto been observed to melt otherwise than at the temperature mentioned.

Recently, Mr. Hadley, of this laboratory, has made the interesting observation that the aldehyde-condensation products of disubstituted hydantoins are capable of existing in isomeric modifications. For example, benzaldiphenylhydantoin (V and VI) occurs in two modifications³ which melt at 152° and 192°, respectively. One form, however, the higher melting, represented the chief product of the reaction. With this result

in hand it immediately became of interest to examine more carefully the products of the reaction when hydantoin undergoes condensation with benzaldehyde. This has now been done and we have made the interesting observation that Ruhemann and Stapleton's *benzalhydantoin* (II) likewise occurs in two isomeric modifications. Both isomers are formed by con-

¹ *J. Chem. Soc.*, 77, 246 (1900).

² *Am. Chem. J.*, 45, 368 (1911).

³ Johnson and Hadley, *THIS JOURNAL*, 37, 171 (1914).

densing hydantoin with benzaldehyde. Ruhemann and Stapleton's¹ hydantoin melting at 220° is the chief product of the reaction as generally observed in our previous experiments.

The isomeric modification (*trans*-benzalhydantoin) was identified in the alcoholic filtrates left after purification of the hydantoin melting at 220° (*cis*-benzalhydantoin). It deposited after concentration of these liquors, and was purified by a fractional crystallization from 95% alcohol. It separated from this solvent in burrs or aggregates of distorted prisms which melted at 246° to a clear oil. This modification is less soluble in alcohol than the isomer melting at 220°.

Calc. for $C_{10}H_9O_2N_2$, N = 14.89; found, N = 14.78.

The yield of this hydantoin melting at 246° is extremely small, being less than 1% of the theoretical. An attempt to prepare this modification by heating the isomer melting at 220° was unsuccessful. The latter was recovered unaltered after heating to the melting point of the higher modification (246°). In the case investigated by Johnson and Hadley¹ the higher melting modification of benzaldiphenylhydantoin (*trans*-form) was the chief product of the reaction. It is, therefore, a very interesting fact that benzaldehyde condenses with hydantoin in an anomalous manner, forming chiefly the lower melting modification of the hydantoin (*cis*-form melting at 220°).

Summary.

Benzalhydantoin (II) occurs in two modifications melting at 220° and 246°, respectively:

NEW HAVEN, CONN.

THE ACTION OF CHLORAL, BROMAL AND BENZALDEHYDE ON THE POLYCYCLIC HYDROCARBONS IN THE PRESENCE OF ALUMINIUM CHLORIDE.

[PART II.]

BY G. B. FRANKFORTER AND W. KRITCHEVSKY.

Received December 14, 1914.

As has already been shown by us² when chloral is brought in contact with benzene or one of its derivatives in the presence of anhydrous aluminium chloride at the ordinary temperature, a violent reaction takes place,

¹ *Loc. cit.*

² *Bull.* 2, "Chemical Studies," University of Minnesota, also abstract, *THIS JOURNAL*, 26, 1511.

resulting in complete decomposition of both the chloral and the hydrocarbon; but when these substances are brought together at a low temperature, zero or below, an entirely different change takes place, resulting in most cases in a condensation reaction resembling very closely the so-called Baeyer reaction in which concentrated sulfuric acid is used as a condensation reagent.

Thionyl chloride and thionyl bromide is treated at 0° with chloral in the presence of aluminium chloride. The following condensation reaction takes place:

or

or

Condensation of Naphthalene with Chloral and Bromal by Means of Aluminium Chloride.—In order to determine whether or not the above condensation reaction could be extended to the more complex aromatic derivatives, experiments were begun on the polycyclic compounds. It was found, as will be shown in the following pages, that aluminium chloride acts in the same manner that it did with the aromatic compounds, forming analogous condensation products. The naphthalene reaction was unusually energetic; so much so, in fact, that great care was necessary in order to prevent total decomposition. In case the temperature was allowed to rise, decomposition began immediately; but if carefully controlled, at zero or below, the condensation reaction was almost quantitative.

α -Dinaphthylidichloroethylene, $(\text{C}_{10}\text{H}_7)_2\text{C}=\text{CCl}_2$.—One molecule of naphthalene and one of chloral were brought together and treated with one molecule of aluminium chloride for several hours, care being taken to keep the temperature at zero or below. After the reaction was completed, the mass was treated with water and finally distilled with steam. The black residue left was removed, extracted with ether and finally distilled *in vacuo*. Excess of naphthalene first sublimed in the condenser at 100° and 60 mm. pressure. The temperature then rapidly rose to 300° at 55 mm. pressure. At 160°, decomposition began with liberation of hydrochloric acid. Finally a thick red oil distilled over at about 300° which later crystallized on the cool walls of the condenser. The residue in the flask completely decomposed at 340°.

The red crystalline mass was removed from the condenser and examined. Treated with hot alcohol, the red color immediately disappeared and a part of the substance dissolved. The part insoluble in alcohol was found to be soluble in benzene. The alcohol-soluble part was crystallized several times from alcohol, when it appeared as transparent needles, m. p. 147–

148°. The molten crystals again took on the characteristic red color already observed in preparation. An examination indicated that the compound was doubtless α -dinaphthylidichloroethylene, the same compound which Grabosky prepared by an entirely different method. As α -dinaphthyltrichloroethane has a melting point of 150°, within but two degrees of the dichloro derivative, analyses were made with the following results:

Calc., C = 75.86, H = 4.02, Cl = 20.12; found, C = 75.80, H = 4.10, Cl = 20.02

The above analyses leave no doubt as to the compound being the ethylene derivative.

β -Dinaphthylidichloroethylene, $(C_{10}H_7)_2C=CCl_2$.—The part in the above experiment which was found to be insoluble in alcohol was dissolved in benzene and allowed to evaporate when the substance crystallized out as white glistening crystals. The last traces of benzene and also traces of the α -compound were removed by washing with alcohol. The substance thus purified had a melting point of 219°. This substance also corresponds to the β -dinaphthylidichloroethylene which Grabosky prepared by an entirely different method.

β -Dinaphthylidibromoethylene, $(C_{10}H_7)_2C=CBr_2$.—As has already been stated, when aluminium bromide is added to bromal in the presence of a hydrocarbon, no reaction takes place; but when aluminium chloride is substituted for the bromide, a vigorous reaction takes place, requiring a freezing temperature in order to prevent complete decomposition. Two molecules of naphthalene were treated with one and a half of bromal and one molecule of aluminium chloride added, care being taken to keep the temperature at 0°, as the reaction became violent liberating hydrochloric acid gas if the temperature was allowed to rise to 10°. After keeping the temperature at 0° for three days the reaction seemed to be complete. The whole mass was poured into water in order to remove the aluminium chloride and the excess of bromal. The residue was then subjected to steam distillation. The dark residue left after steam distillation was dissolved in ether and then washed with a little dilute caustic soda solution. The ether solution was then removed, the ether evaporated and the residue distilled *in vacuo*. The first part distilled over between 60° and 120° at 10 mm. pressure as a perfectly colorless liquid. It contained both bromal and naphthalene. Between 120° and 250° a small quantity of yellow oil passed over. It had a distinct phenol odor. Between 250° and 320° decomposition began with the liberation of hydrochloric acid, while a yellow liquid distilled over and solidified in the neck of the condenser. The residue left in the flask was completely decomposed at 320°.

The crystalline substance was removed from the condenser and treated with cold alcohol, in which it was found to be insoluble. It is slightly soluble in hot alcohol. The insoluble part from the hot alcohol was

recrystallized several times from benzene. The purified substance had a melting point of $223-225^{\circ}$.

Analyses give the following:

Calc. for $(C_{10}H_7)_2C=CCl_2$: C = 60.27, H = 3.31, Cl = 36.53; found, C = 60.20, H = 3.31, Br = 36.83 and 36.66

The substance which dissolved in alcohol was found to be aummy mass on evaporating off the alcohol.

The Action of Chloral on Anthracene in the Presence of Aluminium Chloride.—The fact that chlor condensation products were obtained from naphthalene and its derivatives by treating with aluminium chloride led to preliminary experiments along the same line with anthracene.

Dianthracenedichloroethylene, $(C_{14}H_9)_2C=CCl_2$.—Following out the method already described, one molecule of anthracene was suspended in ten volumes of petroleum ether, cooled to 0° and treated with one and a quarter molecules of chloral and, under vigorous stirring, one molecule of aluminium chloride was added. The temperature was not allowed to rise above 10° during the reaction. After the chloride had been added, the stirring was continued for several hours and the temperature allowed to gradually rise to 20° . The reaction mixture was stirred for a day at room temperature the reaction seemed to be complete. The petroleum ether was distilled off and the residue treated with water in order to dissolve the chloride and the unchanged chloral. The black residue which remained was purified by steam distillation and treated with alcohol and ether in order to remove last traces of anthracene. The substance remaining was dissolved in benzene and precipitated out by means of alcohol. The precipitate thus obtained was a brownish yellow powder. It was found to be insoluble in acids and bases, slightly soluble in alcohol, ether and carbon disulfide but very soluble in chloroform, carbon tetrachloride and benzene. It refused to crystallize from any of the solvents. It did not have a sharp melting point but turned black and began to decompose at 340° . It was purified several times by dissolving in carbon tetrachloride and precipitating with alcohol and also by dissolving in benzene and precipitating with alcohol. From 40 g. of the impure substance, 25 g. were obtained in pure form by reprecipitation.

Calc. for $(C_{14}H_9)_2C=CCl_2$, Cl = 15.84; found, Cl = 16.15, 16.18 and 16.45.

9,10-Anthracenedichloroethylene, $C_{14}H_8=C=CCl_2$.—It was found that when anthracene was treated with chloral and aluminium chloride in the presence of benzene, the reaction appeared to be different from the one already mentioned, in which petroleum ether was used as a solvent. Accordingly, one molecule of anthracene and five molecules of chloral were dissolved in ten times their volume of benzene and treated with one molecule of aluminium chloride at 0° . The reaction which took place resembled,

in some respects, the one in which petroleum ether was used as the solvent. The yellow powder obtained was found to be insoluble in the inorganic solvents, namely, the acids and bases; slightly soluble in alcohol and ether but very soluble in benzene, chloroform and carbon tetrachloride. It refused to crystallize and did not have a sharp melting point. It decomposed at a very high temperature. Analyses of the purified substance gave numbers which correspond to the formula given above.

Calc. for $C_{14}H_8=CH=CCl_2$, C = 70.84, H = 2.95, Cl = 26.12; found, C = 70.74, H = 3.19, Cl = 26.37.

From the analysis given above, it is evident that condensation took place with one molecule of anthracene instead of two as observed in the case of benzene, naphthalene and their derivatives.

In order to determine the position in which the chloral molecule entered the anthracene molecule, the substance was suspended in glacial acetic acid and oxidized with chromium trioxide, using the proportions of the substance acetic acid and chromium trioxide ordinarily given for the oxidation of anthracene to anthraquinone. The powder remained unchanged and no anthraquinone derivatives were formed. It is evident therefore, that the chloral had entered the gamma positions, thus preventing the formation of anthraquinone derivative. Duplicate oxidation experiments were made with pure anthracene, when anthraquinone was readily obtained.

From the above experiments it was evident that the solvent had something to do with the way in which the reaction goes. In order to test out more fully the solvent influence on the reaction, the above experiments were repeated using carbon disulfide as the solvent, when a different compound was obtained.

9,10-Anthracenetrichloroethane, $C_{14}H_8=CH-CCl_2$.—One molecule of anthracene was suspended in ten times its volume of carbon disulfide and treated with one and a half molecules of chloral and one of aluminium chloride. The temperature was kept at 0° . A small amount of hydrochloric acid was liberated. At the end of five or six hours the reaction seemed to be complete. The substance was partially purified by steam distillation and by washing with alcohol. The residue was then treated with ether, in which it was found to be partially soluble. The soluble part was examined and found to be composed of two or more substances which could not be separated. The insoluble part was dissolved in benzene and precipitated by means of alcohol. Thus obtained, the substance appeared as a brown amorphous powder without a distinct melting point. Analyses of the substance indicated that it was not quite pure. The experiment was, therefore, repeated, modifying the process by removing all of the water-soluble substances before treating with alcohol and ether. By dissolving in benzene and precipitating with alcohol several times

it was obtained in pure form. Thus obtained, it was a yellowish brown powder insoluble in all the common solvents except benzene, chloroform, carbon tetrachloride and acetone. It is unchanged by boiling alcoholic potash, concentrated nitric acid and bromine.

Analyses gave the following:

Calc. for $C_{14}H_8=CH-CCl_3$, C = 62.55, H = 2.93, Cl = 34.53; found, C = 63.05, H = 2.76, Cl = 32.50

Complete combustion of the substance was very difficult, owing to the fact that some of the carbon was deposited on the porcelain boat as graphite. This unusual stability may be due to the fact that the chloral radical is joined to the anthracene in the meso position, as was also indicated by the oxidation experiments.

The Action of Bromal on Anthracene in the Presence of Aluminium Chloride and Carbon Disulfide.—Bromal readily reacts with anthracene in the presence of aluminium chloride, especially when carbon disulfide is used as a solvent. As has already been stated, no reaction takes place if aluminium bromide is used instead of the chloride. Furthermore, the temperature must be kept near 0° in order to obtain satisfactory results.

9,10-Anthracenetribromoethane, $C_{14}H_8=CH-CBr_3$.—One molecule of anthracene and two of bromal were dissolved in ten volumes of carbon disulfide and one molecule of aluminium chloride added piece-meal. A very small amount of hydrochloric acid was liberated during the reaction. After the reaction was completed, the whole mass was washed with water until all of the water-soluble substances had been removed. The disulfide solution was separated from the water, treated with alcohol and shaken, when the substance was precipitated as a dark brown powder. It was filtered off, washed with alcohol, dissolved in benzene and reprecipitated with alcohol. By redissolving in benzene and reprecipitating several times, the substance changed to a chocolate-brown powder which did not melt at 360° . It proved to be insoluble in the acids and bases and in alcohol and ether. It is readily soluble, however, in chloroform, carbon tetrachloride and benzene. It is not changed by the ordinary oxidizing reagents; neither is it changed by bromine or alcoholic potash.

Analysis of the purified substance gave the following:

Calc. for $C_{14}H_8=CH-CBr_3$, C = 43.54, H = 2.04, Br = 54.43; found, C = 42.14, H = 2.30, Br = 52.82

Like the anthracene derivatives already mentioned, this substance is characterized by its unusual stability. This characteristic doubtless throws some light on the structure of the molecule, for it at least eliminates the aldol reaction which was observed in connection with the benzene reaction. Furthermore, the fact that no anthraquinone could be obtained by oxidation leads to the belief that chloral is joined to carbon atoms 9 and 10 in the anthracene molecule.

The Action of Chloral on Phenanthrene in the Presence of Aluminium Chloride and Carbon Disulfide.—Chloral reacts readily with phenanthrene in the presence of aluminium chloride. Best results were obtained, however, when carbon disulfide was used as a solvent.

9,10-Phenanthrenetricloroethane, $C_{14}H_8=CH-CCl_3$.—One molecule of phenanthrene was dissolved in two molecules of chloral, ten volumes of carbon disulfide and one molecule of aluminium chloride added. The reaction was violent and a large amount of hydrochloric acid liberated even though the temperature was kept at 0° . After the reaction was completed and the whole mass purified by means of water, alcohol and ether, it was finally obtained in pure form by dissolving in benzene and reprecipitating several times by means of alcohol. The substance thus obtained was a yellow powder without a definite melting point, but decomposing at a high temperature.

Calc. for $C_{14}H_8=CH-CCl_3$, C = 62.55, H = 2.93, Cl = 34.53; found, C = 62.59, H = 2.96, Cl = 34.76.

It was found to be insoluble in all of the common solvents except chloroform, carbon tetrachloride and benzene. It remains unchanged by treating with concentrated nitric acid and the common oxidizing and reducing reagents. It is evident again that the chloral has attached itself to the phenanthrene molecule in the meso position.

The Action of Bromal on Phenanthrene in the Presence of Aluminium Chloride and Carbon Disulfide.—Bromal does not combine with phenanthrene in the presence of aluminium bromide; however, when the chloride is substituted for the bromide, a vigorous reaction takes place even though the temperature is kept at 0° .

9,10-Phenanthrenetribromoethane, $C_{14}H_8=CH-CBr_3$.—One molecule of phenanthrene was dissolved in two of bromal, ten volumes of carbon disulfide and one molecule of aluminium chloride added. A vigorous reaction began immediately and a large amount of hydrochloric acid was liberated. After the reaction was complete, the compound formed was purified with water and alcohol as previously stated and finally reprecipitated several times from benzene by the addition of alcohol. The compound thus obtained was a yellow powder like the one previously mentioned; neither could it be obtained from any of the solvents in crystalline form. Like the previous compound mentioned it is soluble only in chloroform, carbon tetrachloride and benzene. It does not change when heated at 300° .

Analyses of the purified substance gave the following:

Calc. for $C_{14}H_8=CH-CBr_3$, C = 43.54, H = 2.04, Br = 54.43; found, C = 43.89, H = 2.45, Br = 54.05.

Like its analogous compounds, it remains unchanged in the presence of the common oxidizing and reducing reagents.

The Action of Benzaldehyde on Phenanthrene in the Presence of Aluminium Chloride and Carbon Disulfide.—One molecule of phenanthrene was dissolved in one and a half of benzaldehyde and five volumes of carbon disulfide. One and a half molecules of aluminium chloride were then cautiously added. After the reaction was completed and the whole mass purified by means of water, alcohol and ether, it was further purified by dissolving in benzene and reprecipitating several times with alcohol. On adding about half of the necessary amount of alcohol to completely precipitate out the substance from the benzene, and filtering, the substance may be separated into two distinct compounds: the one precipitated out by the alcohol as a resin of unknown composition, and the other a brown powder obtained by evaporating off the alcohol and benzene.

Diphenanthrenephenylmethane, $(C_{14}H_9)_2 : CH.C_6H_5$.—The above-mentioned brown powder was redissolved and reprecipitated several times by means of excess of alcohol. Analysis of the substance gave the following:

Calc. for $(C_{14}H_9)_2CHC_6H_5$, C = 94.59, H = 5.41; found, C = 94.19, H = 5.28

Molecular weight determination gave 445; calc. 444.

The purified substance was dark yellow powder melting and decomposing at 165° .

Dibenzalmesotriphenanthrene, $(C_6H_5CH)_2(C_{14}H_9)(C_{14}H_9)_2$.—The resinous substance above mentioned was purified several times by dissolving in benzene and reprecipitating by means of alcohol. The substance was finally obtained as a brown powder which melted at $195-197^\circ$ with decomposition.

Molecular weight determination gave 705; calc. 710.

We were unable to obtain any of these complex compounds in crystalline form. However, by reprecipitating several times as has already been indicated, they were from all appearances in pure form. It is unusual that these hydrocarbons, some of them at least, have a distinct color. Some of these colored substances are under investigation at the present time.

THE SEPARATION OF THE CONSTITUENTS IN A NATURAL GAS FROM WHICH GASOLINE IS CONDENSED.

BY GEORGE A. BURRELL AND FRANK M. SEIBERT.

Received December 7, 1914.

In a previous communication¹ to THIS JOURNAL the authors showed

¹ THIS JOURNAL, 36, 1537 (1914).

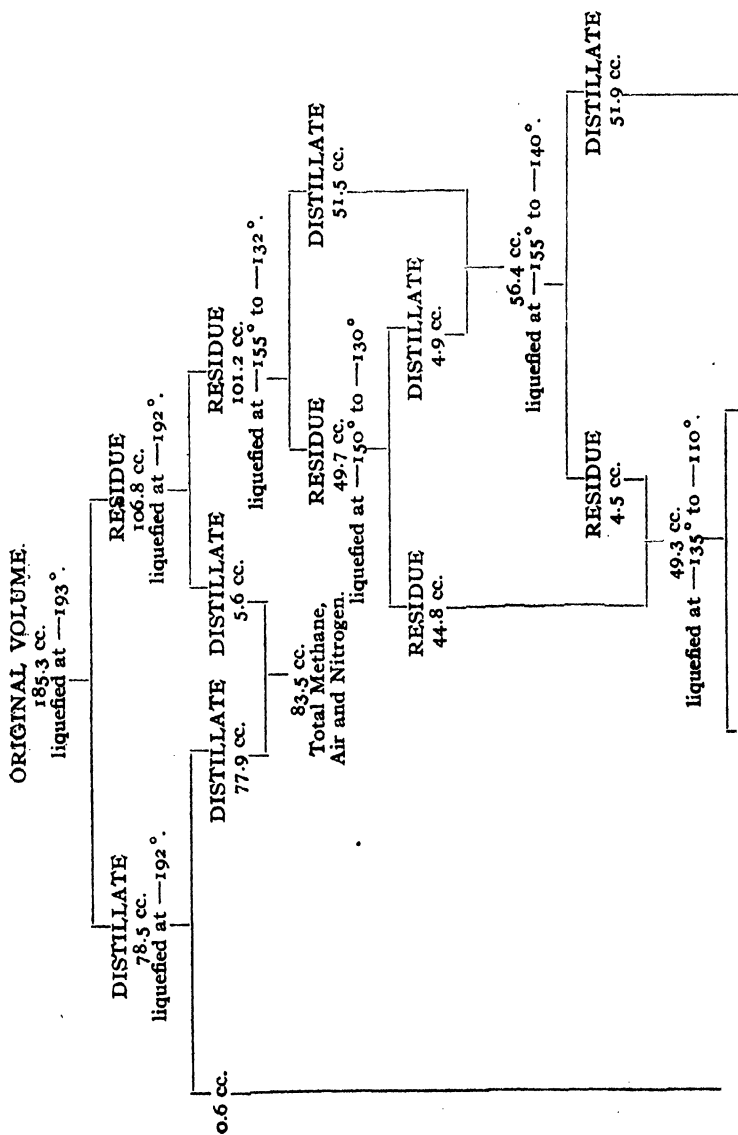

a method of separating the constituents in natural gas by fractional distillation in a vacuum at low temperatures. The gas experimented with was that used in Pittsburgh. Methane predominates in it with only small proportions of the higher paraffins. Not enough of the latter are present for the commercial condensation of gasoline. In this paper are shown the constituents in a natural gas that was obtained at a plant where the gas is treated for the condensation of gasoline. The procedure of separation is the same as that used in separating the constituents in the natural gas of Pittsburgh. Fig. 1 shows the various steps in the work. The original volume of the sample was 185.3 cc. At the temperature of liquid air 78.5 cc. of gas were removed, leaving a residue of 106.8 cc. Both the residue and distillate were reliquefied to obtain, as shown, by analysis pure methane mixed with air and nitrogen. This distillate amounted to 83.5 cc. Air had been accidentally introduced into the sample prior to the experiment. The final analysis was calculated air-free as given below to show the constituents originally present in the gas.

Second Series of Fractionations.—After the removal of the methane there remained a residue of 101.2 cc. containing ethane and higher paraffin hydrocarbons. This was liquefied and distilled and the distillate and residue from it liquefied and distilled again until finally at a temperature not higher than -140° there was obtained a distillate of 51.9 cc. that was pure ethane as nearly as could be determined by analysis. To this portion was added 0.6 cc. of ethane obtained in the first series of fractionations when the methane was separated. There resulted a total of 52.5 cc. ethane.

Third Series of Fractionations.—After the removal of the ethane there remained a total residue of 49.3 cc. consisting of propane and the higher paraffin hydrocarbons. The final fractionation in this series was made at a temperature not higher than -120° and resulted in obtaining 34.1 cc. of pure propane. It will be noted that the fractionations were carried to a point where only a small quantity (1.8 cc.) of propane was finally obtained.

Fourth Series of Fractionations.—After the removal of the propane there remained a residue of 15.2 cc. that contained the butanes and higher paraffin hydrocarbons. A separation of this residue into two portions was made by removing some gas with the pump at a temperature not higher than -95° . An analysis of the distillate was made, the result of which indicated butane chiefly. It is certain that some of the butanes remained in the residue and that the distillate of 9.3 cc. contained at least a small quantity of the pentanes, etc., hence it is better to simply call the 15.2 cc. residue butanes and higher paraffin hydrocarbons.

There follows the results of the fractionation analysis showing, under *A*, the paraffins in cubic centimeters, under *B*, the analysis in per cent. of the sample with air, and under *C*, the analysis calculated air-free. The

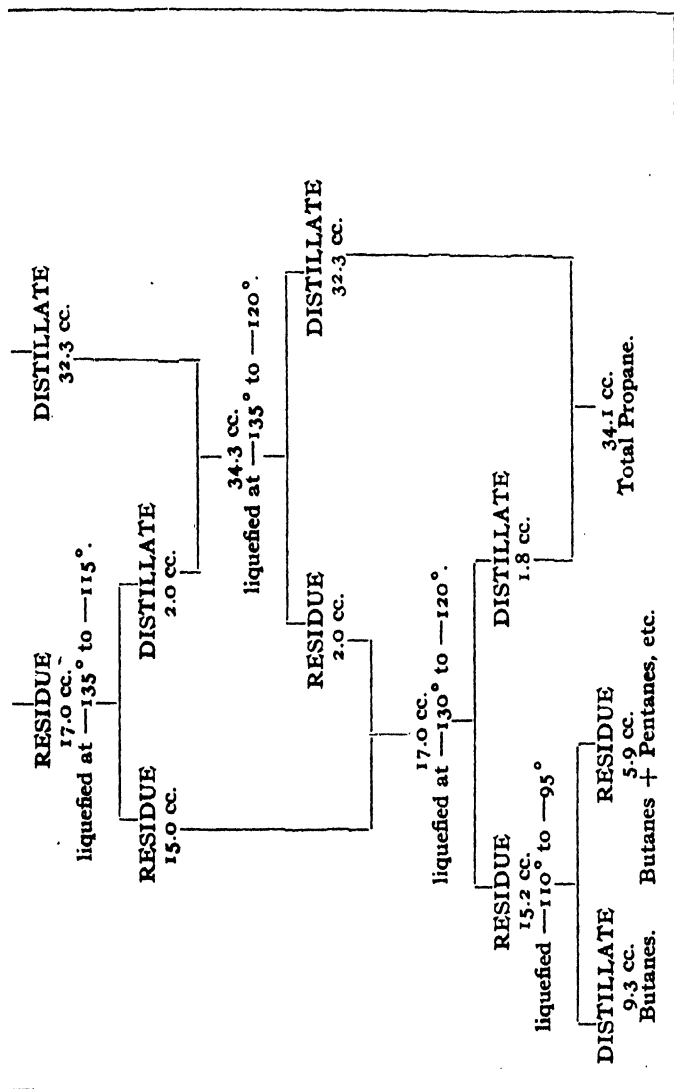

Fig. 1.—Fractionation analyses of natural gas.

air is foreign to the natural gas as it occurs in the wells and should, therefore, be eliminated. There is, however, about 1.0% nitrogen and about 0.03% carbon dioxide which are not shown in the analysis as presented.

FRACTIONATION OF NATURAL GAS FROM WHICH GASOLINE IS CONDENSED.

	A. Cc.	B. Per cent.	C. Per cent.
Air + nitrogen.....	24.5	13.2
Methane.....	59.0	31.9	36.8
Ethane.....	52.5	28.3	32.6
Propane.....	34.1	18.4	21.1
Butanes (chiefly).....	9.3	5.0	5.8
Pentanes and hexanes.....	5.9	3.2	3.7
Total.....	185.3	100.00	100.0

For comparison there is shown the fractionation analysis of the natural gas of Pittsburgh.

FRACTIONATION ANALYSIS OF THE NATURAL GAS OF PITTSBURGH.

Constituents.	Per cent.
Nitrogen.....	1.6 ¹
Methane.....	84.7
Ethane.....	9.4
Propane.....	3.0
Chiefly butane.....	1.3

Total..... 100.0

Considerable difference will be noted between the quantity of the different paraffins in this gas mixture and in the one first described. The natural gas of Pittsburgh is used in immense quantities in the east for domestic and other purposes. The other represents a gas used for the condensation of gasoline. Temperatures are in degrees centigrade. Experimental details are shown in a previous communication.²

PITTSBURGH, PA.

EXPERIMENTS ON THE NATURE OF THE PHOTOGENIC SUBSTANCE IN THE FIREFLY.

By E. NEWTON HARVEY.

Received December 19, 1914.

Previous research on the subject of biophotogenesis has shown that at least three factors are necessary for the production of light, namely, water, oxygen and a photogenic substance. A fourth factor is probably also involved, an oxidizing enzyme, as in other organic oxidations. Concerning this enzyme nothing is known, at least nothing definite in the case of the firefly. Indeed Kastle's³ observations indicate that in the firefly

¹ Includes a trace of carbon dioxide, about 0.03%.

² *Loc. cit.*

³ J. H. Kastle, Hygienic Lab., Washington, D. C., *Bull.* 59, 92 (1910).

no direct oxidizing enzyme (oxygenase) but only small amounts of an indirect oxidizing enzyme (peroxidase) and a catalase are present.

The old observation that many luminous tissues can be dried and ground up and will phosphoresce, when water containing oxygen is again added, gives us a simple chemical method of investigating the nature of the photogenic material. The dried material may be extracted with water-free solvents (since the photogen does not oxidize in absence of water) and extracted material as well as the residue from evaporation of the filtrate tested for phosphorescence by adding water. Or, the dried material may be extracted with oxygen-free aqueous solvents (since the photogen does not oxidize with light production in absence of oxygen) and filtrate and residue tested as before by admitting oxygen. The first method is satisfactory and has indicated that a large number of fat solvents will extract nothing from the dried tissue and yet leave the photogenic material unharmed. Indeed, the material may be extracted with boiling ether for twenty-four hours without impairing its power to phosphoresce. Boiling alcohol does destroy the power to phosphoresce and the nature of its action is discussed below. These results, as well as the previous results of McDermott¹ and Dubois,² using fresh watery material, show conclusively that the photogenic substance is not a fat or fat-like body of any kind.

The second method—that of extraction with oxygen-free water solutions—is not satisfactory because the photogenic substance breaks up, or at least loses its power to phosphoresce, on standing in contact with water for any length of time *even if no oxygen is present*. Many attempts were made to extract the dried material with aqueous solvents and filter the extract in absence of oxygen before it was recognized that such attempts were futile because of the instability of the photogenic substance in oxygen-free water.

My experiments were begun in the winter of 1913 on firefly material collected at Princeton, N. J., and dried over CaCl_2 in a vacuum. (See preliminary note, Harvey.³) I am greatly indebted also to Mr. F. Alex. McDermott of the Mellon Institute, University of Pittsburgh, for an additional supply of material with which the work was continued. Mr. McDermott has been making experiments along similar lines with a somewhat different apparatus and his results are likewise published in this journal.⁴ As luminous material may be found which does not disintegrate in water the apparatus used for oxygen-free extraction is described below.

¹ F. A. McDermott, *THIS JOURNAL*, 33, 1791 (1911); *Smithsonian Report*, 1911, 345.

² *Orig. Comm. 8th Intern. Congr. Appl. Chem.*, 19, 86 (1912).

³ *Science*, 40, 33 (1914).

⁴ *Loc. cit.*

The material to be extracted is placed in the vessel C (Fig. 1), provided with a ground-in stopper connected with a 120° stopcock. The water to be rendered free of oxygen is placed in B after passing hydrogen through stopcock C and closing it. B is connected through A with a hydrogen

Fig. 1.

generator. The hydrogen is passed through potassium hydroxide to remove acid and then over a glowing platinum wire (in A) to remove the last traces of oxygen, a much better method than passing the gas through alkaline pyrogallol. By alternately exhausting B through *b*, connected to an air pump, and refilling with hydrogen several times the water can be quickly rendered free of oxygen. C is then connected to B through *c* and one of the arms of the 120° stopcock (*d*) whose other arm is connected with an air pump. C and the arms of *d* are then exhausted. The 120° stopcock is then turned to connect C and B and *c* is opened, allowing the pressure of the hydrogen to drive the solvent on the material in C. The proper amount of fluid for extraction should be placed in B so that the hydrogen may follow it through and fill the chamber C. Then *d* is closed, when C can be disconnected and shaken during extraction. To filter the extract it is only necessary to connect one of the arms of *d* with a desiccator fitted with funnel and filter rack. When the desiccator is exhausted, C and the desiccator are connected, and the pressure of the hydrogen in C drives the extract onto the filter paper. The firefly photogen begins to phosphoresce when the atmospheric pressure reaches 5–6 mm., which means an oxygen pressure of 1–1.2 mm. Consequently it is necessary to use a good vacuum pump and make connections air tight. I found that small bore lead tubing sealed with Khotinsky cement the best for the purpose.

If one extracts with distilled water for a short time (15 minutes) and then filters, on admitting oxygen the filtrate is found to be dark while the residue on the filter paper shows the bright points of light characteristic of the powder of the firefly. But if the extraction be carried out for an hour or more, neither the filtrate nor the residue will phosphoresce when oxygen is admitted. All of my experiments have been carried out in the dark and the material observed at critical stages (as when the oxygen-free water

was added) to make sure that no light appeared, and always with negative results. But to make sure that no very slow leakage of oxygen into the filtering chamber occurred, I have carried out the extraction in a special tube provided with a capillary sealed off during the extraction. After extracting in this tube for one and one-half hours and admitting oxygen no phosphorescence appeared. Thinking that possibly the photogen dissolved in the extracting fluid did phosphoresce, but only so faintly as to be invisible because distributed through a relatively large volume of extract fluid, the unfiltered extract was evaporated *in vacuo* to a small volume. This can be very easily done by placing the rubber tube from the vacuum pump over the capillary onto the special tube, exhausting, and then breaking the capillary through the walls of the rubber tube to connect with the air pump. Even when concentrated, the extract gave no light on adding oxygen.

The photogen is, therefore, destroyed in distilled water without oxidation. The search for a watery solvent for the photogen becomes then a search for a solvent in which the photogen is stable. The following solutions were tried in addition to distilled water. Extraction was allowed to proceed for from 1 to 1.5 hrs.

1. Ringer's solution (as representing fairly accurately the concentration and composition of the firefly's blood).

2. 0.125 *M* NaCl.

3. Sea water (a mixture of chlorides and sulfates of Na, K, Ca and Mg).

4. 5% NaCl.

5. 0.05 *M* NaOH and 0.01 *M* NaOH. The dried, powdered firefly organs will phosphoresce strongly if sprinkled on the surface of 0.1 *M* NaOH.

6. 0.02 *M* HCl. Dried firefly powder will phosphoresce on 0.0125 *M* HCl and on 0.025 *M* HCl, but less brilliantly. Only one or two bright dots appear on 0.05 *M* HCl and no phosphorescence occurs on 0.1 *M* HCl. If neutralized within two minutes after contact with the acid, the light does not appear in the 0.1 *M* HCl treated material nor become brighter in the 0.05 *M* and 0.025 *M* treated material.

In each case after extraction, oxygen was admitted and the solution shaken, yet in no case did light appear either in the undissolved residue or in the solution. The 0.02 *M* HCl extract was also neutralized as it is well known that the acid prevents biophotogenesis. The conditions of phosphorescence in the firefly are, therefore, more complex than at first supposed. Either the photogen, the enzymes, the enzyme activators or all three, undergo changes, which are not oxidative in nature, when the material stands in contact with water for a time sufficient to dissolve out the luminous material. Both McDermott's results and mine agree perfectly and while negative and disappointing they are deemed worthy of publication as indicating that water, oxygen and a photogenic

substance are not the only factors involved in light production and also as showing the instability of the photogen.

My work with water-free solvents has been confined to those listed in Table I, which gives also the time of extraction, temperature and results.

TABLE I.

Ethyl butyrate.....	20	48	very faint ¹	—

A plus sign indicates phosphorescence when water is added and a minus sign indicates no phosphorescence. Both the original extracted material and the residue of the filtered extract evaporated to dryness were examined. The results indicate that the photogenic substance is not a fat or oil and also not a lecithin. I am aware that the lecithins are difficult to extract *in toto* from the cell, but this can be accomplished by a mixture of hot ether and alcohol, and yet a mixture of hot ether and alcohol will extract nothing which will phosphoresce from the firefly powder. We may safely say that the photogen is not a lecithin.

Of all the solvents tried only hot alcohol and cold amyl alcohol and ethyl butyrate gave results that would indicate a possible solution of the photogenic substance. And yet there is nothing in the filtrate residue that will phosphoresce when water or a neutralized 3% solution of H_2O_2 is added. Thinking that oxidizing enzymes might be necessary and that these had not been extracted by the fat solvents although the photogen had, the filtrate was also tested by adding a water extract of firefly organs, fresh or preserved with toluol or chloroform, and also by potato-juice which contains considerable quantities of oxidizing enzymes. In no case was phosphorescence observed. The boiling ethyl alcohol,² cold amyl alcohol, and ethyl butyrate must, therefore, break up the photogen. It is the alcohol itself and not the temperature (78.4°) of boiling alcohol which is

¹ The material was washed with ether to remove the amyl alcohol and ethyl butyrate.

² The 99.8% absolute alcohol was distilled over metallic calcium and collected in a receiver protected from the air by $CaCl_2$ in order to remove the last traces of water.

responsible for the destruction of the photogen as the dried powder will withstand this temperature for 24 hrs. without any appreciable diminution in its power to phosphoresce. McDermott finds that liquid sulfur dioxide and liquid ammonia also destroy the photogenic power.

The powder obtained by drying cultures of luminous bacteria behaves similarly to the firefly material.

These results indicate that it will be a vastly more difficult problem to isolate and identify the photogenic substance than might at first be supposed.

PRINCETON UNIVERSITY, PRINCETON, N. J.

EXPERIMENTS ON THE NATURE OF THE PHOTOGENIC PROCESSES IN THE LAMPYRIDAE.

By F. ALEX. McDERMOTT.

Received December 19, 1914.

During the summer of 1914, the writer made some tests along the same line as described in the preceding paper by Harvey (p. 396), and he also attempted to obtain evidence of the breaking down of nucleic acids during the photogenic process, as suggested by Lund.¹ While the results are mainly negative, they are of interest as confirming Harvey's experiences. The obvious limitations to such work, owing to the restricted amount of material available at one time, is a serious handicap to very extensive results. Most of the present writer's experiments were made on material prepared from *Photinus pyralis* and *P. castus*; some of the material from the former species had been collected at Washington, D. C., in the summer of 1911, and, after drying *in vacuo* over sulfuric acid, had been sealed *in vacuo* in small flasks. This latter material was very kindly supplied to me by Professor J. H. Kastle, Director of the Kentucky Agricultural Experiment Station. It was apparently as active as when first prepared.

Extractions were made in oxygen-free natural gas. After grinding, the tissue to be tested was placed in a small separatory funnel which had been filled with gas which had been passed through pyrogallol solution; the washed gas was allowed to pass through the funnel for some time to sweep out any air which may have entered when the tissue was placed in the funnel. For the filtering, a vacuum desiccator was fitted up with a small beaker, a wire funnel support and a small funnel with a folded filter. The desiccator was connected to the gas supply for some time in order to remove all the air. The solvent to be used was placed in a small Erlenmeyer flask provided with a tightly fitting stopper bearing two small bore stopcocks. The washed gas was passed through this flask for some time after the solvent had been run in, and the solvent was then heated

¹ Lund, *J. Exper. Zool.*, **11**, 415 (1911).

slowly to the boiling point, and kept boiling quietly for about a minute, *when it was allowed to cool slowly in a current of the gas (except in those cases in which it was used hot).* When cool, both stopcocks were closed and the outgoing tube connected to the inlet of the separatory containing the material to be tested; both tubes were well blown out with the gas before connection, and kept surrounded by a current of gas while being connected; the outgoing stopcock on the flask and the ingoing on the separatory were then opened, then the ingoing stopcock on the solvent flask, and finally the outgoing on the separatory, the solvent being run into the separatory by the pressure of the gas, when the small flask was inverted. The stopcocks on the separatory were then closed and the solvent flask disconnected. The separatory was shaken thoroughly, so that the tissue would be fully exposed to the action of the solvent; in some experiments filtration was done immediately, while in other cases the tissue was allowed to stand in the solvent for some time, usually with occasional shaking.

Fifteen to twenty of the dried luminous segments, weighing about 0.05 to 0.07 g., were usually used in a test. The filtrate and residue were usually tested by first exposing to the air and then by adding hydrogen peroxide (3% solution) always in a dark room, the eyes being allowed to become accustomed to the darkness for at least ten minutes before applying the test. In no case was the emission of light from the filtrate observed, though in short, cold extractions with alkali some activity of the residual material was noticed—due to larger fragments of the material which had not been thoroughly penetrated by the solvent.

The following are some of the combinations which were used:

1. 15 organs; 25 cc. 0.15 N H_2SO_4 ; solvent used cold, and allowed to stand fifteen minutes after shaking before filtration: No light at any stage.
2. 15 organs; 20 cc. 0.03 N $NaOH$; solvent used cold, and allowed to stand fifteen minutes after shaking before filtration. No light on adding solvent to tissue; faint light on running liquid on filter: Filtration very slow; no light on testing residue and filtrate four hours later.
3. 15 organs; 20 cc. 0.05 N $NaOH$; solvent used cold and filtered immediately after shaking: No light at any stage.
4. 15 organs; 25 cc. 0.001 N $NaOH$; organs crushed rather than ground; solvent applied hot and filtered immediately after shaking: No light at any stage.
5. 4 repeated, using cold alkali; larger pieces of tissue glowed on treatment of residue with 3% H_2O_2 on filter; no light from fine material on the filter, nor from the filtrate. A very active catalase went into solution in the alkali in this experiment.

All the extracts had the characteristic odor of the insect, which was intensified by the alkali.

A considerable number of experiments were run using alkaline solutions as solvents, with the view that if nucleic acids were present, as suggested by Lund and were active in light production, they might be thus gotten into solution; in no case was an active extract obtained. To examine this

point further, determinations of the total nitrogen in the insects and in the luminous organs, and of the nitrogen, phosphoric acid and carbohydrates in the extracts were attempted. For the determination of the total nitrogen in the insects and in the luminous apparatus, dried specimens of *Photinus castus* collected in Pittsburgh, Pa., were used; this species is quite closely related to *P. pyralis* and it is unlikely that there would be any wide difference in the proportion or distribution of the nitrogen in them.

The mean of two determinations of the total nitrogen in the luminous tissue showed 13.6%, while the mean of two determinations on the remainder of the insect showed 10.3%; this would indicate about 11% N for the whole insect, calculated on the relative weights of the luminous segments and the remainder of the insect. All weights refer to the tissue dried *in vacuo* over sulfuric acid. The low figure for the total nitrogen of the insect is probably accounted for by the relatively large amount of chitin, while the high figure for the luminous tissue is undoubtedly due to the deposits of uric acid or closely related compounds which form the so-called reflecting layer, constituting the larger part of the bulk of the dry material from the luminous segments.

To test the possible effect of the photogenic processes on the amount of soluble nitrogen, phosphoric acid and carbohydrate, two experiments were run in parallel, using the tissue of *Photinus pyralis*. In the first test, (A), 0.146 g. of the ground dry tissue was treated with 20 cc. of hot 0.075 N H_2SO_4 , in natural gas; 1 cc. of 3% hydrogen peroxide and 20 cc. of water were then added, the mixture boiled and filtered and the filtrate and washings made up to 50 cc. In the second (B), 0.179 g. of the ground dry tissue was treated with 1 cc. of 3% hydrogen peroxide and 20 cc. of water in the air, and allowed to stand till the action and light-emission had ceased; 20 cc. of 0.075 N H_2SO_4 were then added and the solution boiled, filtered, and made up to 50 cc. By this means the material in the first test, (A), was kept from light production, while in the second test (B) the light-producing power was expended. The nitrogen was determined in 25 cc. portions of each of these filtrates, while a portion of the remainder was used for the titration of P_2O_5 with uranium acetate. Tests for optical activity were negative on both filtrates, which is taken to indicate the absence of significant quantities of carbohydrates. The results of the N and P_2O_5 determinations are given below:

Test.	Per cent. of weight of dry tissue taken.	
	N in solution, by Kjeldahl.	P_2O_5 in solution, by uranium acetate.
A.....	4.81	0.515
B.....	4.14	0.420

These figures do not show as great a difference as might be expected were the photogenic process accompanied by any extensive breaking down

of nucleic acids, and the differences, indeed, are in the opposite direction to what would be expected under such circumstances.

From the evidence of the present experiments it is that the deposits of purine substances which form the so-called reflecting layer of the photogenic organs of the Lampyridae cannot be traced satisfactorily to the breaking down of nucleic acids. In agreement with the work of Harvey, reported in the preceding paper, dilute acid and alkaline solutions, hot or cold, fail to extract a light-producing substance from the dry tissues of these insects, even when used in the entire absence of oxygen, and such solutions rapidly destroy the photogenic activity of the dry tissue.

NEW BOOKS.

Qualitative Chemical Analysis. By CHALFANT E. BIVINS. New York: John Wiley and Sons. Price, \$1.00.

This manual is one of a series of loose-leaf laboratory manuals, edited by J. M. Jameson. The author has made no attempt to depart from conventional tests and separations. The book has, however, many excellent features. The directions are clear and easily followed; the discussion of procedures, explanatory notes, practice equations, and questions on the groups are excellent, and should be helpful to both teacher and student. The treatment of the analysis of alloys and metals is particularly good.

Comparatively little in the way of discussion of the principles of qualitative analysis has been attempted. The little that is given is so brief as to be of inconsiderable value. The statement that "*All the reactions of precipitation are ionic*, that is, are made by ions," would hardly be accepted even by many of the most ardent supporters of the theory of Electrolytic Dissociation. Likewise, the statement that "Oxidation is an increase in valence, and reduction a decrease in valence," leaves the student with an incorrect idea of these processes. No mention is made of the law of Mass Action and its applications.

For teachers who prefer to develop these subjects in the class room and wish a good laboratory guide, this laboratory manual can be used profitably.

JAMES H. WALTON, JR.

Food Products. By HENRY C. SHERMAN, PH.D. ix + 594 pp.; illustrated. New York: The Macmillan Company, 1914. Price, \$2.75.

During the last ten or fifteen years people have heard much about the origin and composition of foods and of laws to protect the purity of foods. Much of this discussion has been timely and it has acquainted the lay citizen with a class of facts which at one time appeared to be of interest to the food expert only. The lengthy papers and treatises on the somewhat

disagreeable topic of food adulteration have pretty thoroughly cleared the atmosphere over this field and have left as a desired result the assurance, that while there has been some adulteration in certain limited lines of food products, the extent of this has been far less than the rather lurid statements of overzealous writers would lead us to believe. Rational legislation has led to a pretty effectual check on the frauds which were attempted. The various discussions have led recently to the publication of several books which have the object of making different classes of readers acquainted with the essential facts regarding the production, control, and distribution of foods. The reviewer has had occasion to call attention to one of these, "The Source, Chemistry and Use of Food Products," by Professor Bailey, in a recent number of *THIS JOURNAL*. This book was intended primarily for students in certain grades of schools and colleges. The present book by Professor Sherman covers in a measure part of the same ground, but the discussion is such as to make it useful to a different group of readers.

Professor Sherman is the author of another work dealing with the subject of food as related to nutrition. In this book we are presented with another class of relations; the source of foods, the conditions of marketing, the purity of the products as they reach the consumer and the manufacture of canned or otherwise modified foods are treated in detail. The general character of the discussion makes the book more valuable to the chemist or food official than to the student or lay reader.

In different chapters practically the whole range of American foods is covered, and in a satisfactory manner. Appended to each chapter voluminous literature references are given and these seem full enough to satisfy the reader who may wish the original details of the discussions condensed in the text. Practically all that is recent and valuable in the literature of foods appears to be contained in these reference lists.

The second chapter deals with the subject of food legislation in a fair and non-partisan manner while in a long appendix the rules and regulations relating to the enforcement of the Food and Drugs Act are given in full, as are also the more important Food Inspection Decisions (F. I. D. bulletins) of the United States Department of Agriculture. The meat inspection laws and other laws are also given. Numerous tables throughout the book give the best-known results on the composition of various foods.

On the whole, the reviewer must express a very favorable opinion as to the scope and treatment of the material presented. J. H. LONG.

Methods of Quantitative Organic Analysis. By P. C. R. KINGSCOTT AND R. S. G. KNIGHT. New York: Longmans, Green and Co. 1914. xvi + 283 pp. Price, \$2.00 net.

The arrangement adopted in the book is based on a series of six lectures which the authors attended as students during the session of 1911-

1912 at the Imperial College of Science and Technology, London. In the first chapter is described the determination of molecular weights by physical methods; the ones considered are those of Victor Meyer, Bleier and Kohn, Dumas, Hofmann, and the cryoscopic methods as developed by Beckmann, Landsberger, and Walker. The second chapter deals with ultimate analysis. In addition to the methods of Liebig, Dennstedt, Dumas, Kjeldahl, and Carius, descriptions are given of the more recently described methods for the determination of oxygen, sulfur, halogens, phosphorus, arsenic, and antimony. The quantitative estimation of typical groups is considered in the third chapter; a large number of methods for determining the following groups are given: carboxyl, amino, substituted amino, imino, substituted imino, nitro, and carbonyl. The final chapter, which covers about one-half the pages in the book, is devoted to the description of processes for the quantitative determination of certain compounds of technical importance; these include carbohydrates, certain dyes, oils, fats, waxes, alkaloids, alcohols, phenols, acids, aldehydes, ketones, amines, chloroform, iodoform, chloral, ether, acetylenes, anthracene, vinegar, and wood-naphtha. Where such a wide field is covered it is evident that the treatment given to each topic must be very brief. In the case of most of the methods described, however, sufficient details are given to make it possible to carry out the method. It has, apparently, been the aim of the authors to include as many different processes as possible; for this reason the book is a valuable source of references to the literature.

(Founded by Ira Remsen)

TWENTY-SECOND ANNUAL REPORT OF COMMITTEE ON ATOMIC WEIGHTS. DETERMINATIONS PUBLISHED DURING 1914.

BY GREGORY PAUL BAXTER.

Received January 21, 1915.

During the past year reports of investigations upon many of the most used and important atomic weights have been published. The work upon carbon, sulfur, iodine, and the radio-elements, uranium and lead, is particularly interesting and significant.

Oxygen.—In the report for 1913 some gas density determinations by Scheuer¹ were overlooked. Oxygen was prepared from potassium permanganate and potassium chlorate, and after purification was fractionally distilled. The value obtained for the weight of the normal liter is a few units higher in the sixth figure than the one commonly assumed.

WEIGHT OF NORMAL LITER OF O₂.

From KMnO ₄ .		From KClO ₃ .	
1.42908	1.42899	1.42889	1.42919
1.42888	1.42922	1.42904	1.42909
1.42924	1.42886	1.42921	1.42895
1.42911	1.42904	1.42898	1.42911
1.42913	1.42906	1.42909	1.42902
1.42889	1.42921	1.42897	1.42914
Mean, 1.42906		Mean, 1.42906	
Mean, 1.42906			

¹ *Anzeiger d. k. Akad. Wien*, 50, 378 (1913).

Nitrogen.—Scheuer also found the density of nitric oxide, using carefully purified gas.

WEIGHT OF NORMAL LITER OF NO.

1.34002	1.34008	1.34019	1.34014
1.34028	1.34013	1.33994	1.34031
1.34022	1.34015	1.34021	1.34017
1.34004	1.34017	1.34023	1.33995
Mean, 1.34014			

Computed by the method of limiting densities, $N = 14.004$.

Chlorine.—For hydrochloric acid Scheuer obtained the following results:

WEIGHT OF NORMAL LITER OF HCl.

1.63925	1.63931	1.63910	1.63897
1.63894	1.63908	1.63929	1.63923
1.63912	1.63925	1.63918	1.63913
1.63915	1.63937	1.63915	1.63920
Mean, 1.63917			

Computed by the method of limiting densities, $HCl = 36.468$ and $Cl = 35.460$.

Neon.—Leduc¹ fractionated neon with cocoanut charcoal at low temperatures, and, using a 600 cc. globe, in two experiments found the gas to be 0.6964 and 0.6958 times as heavy as air at 0°. Allowance for a slight amount of impurity was made by taking the density as 0.695. From this value and the one 0.06948 for hydrogen, the atomic weight of neon is calculated to be 20.15 ($H = 1.0075$).

Carbon.—Timmermans² prepared propane (a) by the action of propyl iodide on "sodium ammonium" and (b) by the action of sodium on propyl cyanide. The gas was liquefied and fractionally distilled. The weights of the normal liter, found by the globe method, are given below:

(a)			
Volume of globe	564.88 cc.	455.77 cc.	351.91 cc.
	2.02021	2.01928	2.01744
	(2.02287)	2.01807	2.01970

			2.01957

General mean, 2.01956

¹ *Compt. rend.*, 158, 864 (1914).

² *Ibid.*, 158, 789 (1914).

The other data necessary for computing the molecular weight of propane are now being determined in Geneva.

Richards and Hoover¹ titrated weighed amounts of sodium carbonate, which had been fused in a current of dry carbon dioxide, against weighed amounts of a solution of hydrobromic acid which had been standardized both by titration against the purest silver and by weighing the silver bromide produced. The hydrobromic acid solution was found to be equivalent to 8.3113 g. in vacuum of silver bromide per 100.000 g. in vacuum of solution. Furthermore, the solution of sodium bromide resulting from the neutralization was compared with weighed amounts of silver. The weights in the table are corrected to the vacuum standard and the following atomic weights are assumed:

$$\text{Ag} = 107.880; \text{Br} = 79.916; \text{Na} = 22.995.$$

Weight Na_2CO_3 .	Weight HBr solution.	At. wt. C.	Weight Ag.	At. wt. C.
4.75555	202.744	12.008	9.68023	12.005
4.80081	204.673	12.009	9.77222	12.007
4.88936	208.457	12.004	9.95301	12.001
5.63157	240.119	11.997	11.46316	12.008
4.49516	191.646	12.006	9.15003	12.007
4.86256	207.307	12.008	9.89811	12.004

Mean, 12.005

Mean, 12.005

Sulfur.—Richards and Hoover² also neutralized weighed amounts of sodium carbonate with dilute sulfuric acid. The solution was evaporated to small bulk and transferred to a weighed quartz flask, and after evaporation of the solution to dryness the residual sodium sulfate was fused. Vacuum weights are given and the atomic weights of carbon and sodium are assumed to be 12.005 and 22.995, respectively.

Weight Na_2CO_3 .	Weight Na_2SO_4 .	At. wt. S.
5.25191	7.03829	32.058
4.50977	6.04382	32.060
5.04233	6.75737	32.057
3.67340	4.92304	32.063
4.18724	5.61151	32.059
4.55100	6.09916	32.062

Mean, 32.060

Silver.—Richards and Cox³ have published further details of their experiments which show that lithium perchlorate, as prepared by Richards and Willard in their work upon the atomic weights of lithium and silver, is free from moisture. The question as to whether the atomic weight of silver is as low as 107.87 certainly is still an open one.

¹ THIS JOURNAL, 37, 95 (1915).

² *Ibid.*, 37, 108 (1915).

³ *Ibid.*, 36, 819 (1914).

Iodine.—Bates and Vinal¹ made a very careful comparison of the silver and iodine coulometers, using them in series. The silver coulometers were of Smith's "new type" and the "porous pot" varieties; the iodine coulometers of the form devised by Washburn and Bates, the iodine set free being titrated by means of an arsenite solution which had been standardized with weighed amounts of iodine. In the following tables each weight is the mean from several coulometers run in series. Vacuum corrections are applied to the weights of iodine and presumably to the weights of silver. $\text{Ag} = 107.880$.

Weight silver.	Weight iodine.	At. wt. I.
(4. 10582)	(4. 82959)	(126.897)
(4. 10469)	(4. 82862)	(126.907)
4.09903	4.82224	126.914

4.10523	4.82851	126.887
4.12310	4.84942	126.884
4.10475	4.82860	126.904
4.18424	4.92130	126.883
4.10027	4.82247	126.882
4.10516	4.82844	126.887

Mean of last eight experiments, 126.894

Bates and Vinal point out that this result is subject to correction for inclusions of electrolyte by the silver deposits. While Rosa, Vinal and McDaniel² have recently expressed the opinion that highly crystalline deposits from the purest silver nitrate solutions do not contain significant inclusions, Richards and Anderegg³ have found the inclusions of electrolyte to amount to from 0.004 to 0.035% of the weight of silver, according to conditions. These proportions are somewhat larger than those recently found by Hulett. Richards and Anderegg point out that all atomic weights determined electrolytically in the past by comparison with silver coulometers are therefore in error, by amounts impossible of accurate estimation because of the irregular nature of the inclusions. If, however, an average correction, as found by Richards and Anderegg, of 0.015% is applied to Bates and Vinal's results, the atomic weight of iodine becomes 126.913, a value in much better agreement with the most recent gravimetric determination by Baxter, 126.932.

Guichard⁴ also has compared the atomic weight of iodine directly with that of oxygen by decomposing known weights of iodine pentoxide and weighing the products. The iodine pentoxide was prepared from iodic acid and was dried at 240° in a vacuum, the iodine was condensed in the decomposition apparatus and weighed, the oxygen was collected and weighed

6.23324	4.73922	1.49333	6.23255	+0.00069
7.08076	5.38441	1.69714	7.08155	—0.00079

The atomic weight of iodine is computed in three ways.

40 $\frac{\text{wt. } I_2}{\text{wt. } O_2}$	40 $\frac{\text{wt. } I_2}{\text{wt. } I_2O_5 - \text{wt. } I_2}$	40 $\frac{\text{wt. } I_2O_5 - \text{wt. } O_2}{\text{wt. } O_2}$
126.88	126.92	126.87
126.90	126.90	126.90
126.94	126.96	126.93
126.94	126.89	126.96
126.91	126.96	126.89
Mean, 126.91	Mean, 126.93	Mean, 126.91
	General mean, 126.92	

No correction is made for moisture retained by the iodine pentoxide. It is noteworthy that the average deficiency of the weights of the products is 0.0028%, a quantity in close agreement with the moisture content of iodine pentoxide dried at the same temperature, as found by Baxter and Tilley,¹ 0.0023%. The second mean is raised, the third lowered by applying this correction. The general mean is not appreciably affected, however.

Guye and Germann² investigated iodine and silver for occluded gases. One gram of iodine was found to contain 0.000013 g. air. One gram of silver, which had been fused in a current of hydrogen, yielded 0.000034 g. carbon monoxide and 0.000008 g. moisture. Neither material was of the highest purity.

Barium.—De Coninck³ determined the proportion of carbon dioxide in barium carbonate by dissolving the salt in acid. The average of five experiments gave $Ba = 137.4$.

Nickel.—De Coninck with Gerard⁴ also has determined the atomic weight of nickel, by reducing the hydrated oxalate in a current of hydrogen.

Weight $NiC_2O_4 \cdot 2H_2O$.	Weight Ni.	At. wt. Ni.
0.4300	0.1380	58.60
0.4730	0.1517	58.54
0.3440	0.1104	58.60
0.3869	0.1241	58.55
0.5161	0.1656	58.58

Mean, 58.57

This value is 0.2 unit higher than the result reported a year ago by Taylor and Hulett, but confirms very closely the recent work of Easley.

Vanadium.—Briscoe and Little¹ synthesized vanadyl chloride from chloride and vanadium trioxide, and separated the product into four portions, A, B, C, D, by fractional distillation, with rejection of the two extreme fractions. Two of the four main fractions, C and D, were further fractionated in the same way into weighed bulbs which were sealed while exhausted. Analysis was effected by decomposition with ammonia, acidification, and comparison with silver. In two cases the silver chloride was collected and weighed. Vacuum corrections are applied. $\text{Ag} = 107.880$; $\text{Cl} = 35.457$.

This result agrees closely with the value recently found by McAdam, 50.96.

Tellurium.—Still another attempt has been made to separate from tellurium a related element of higher atomic weight. Dennis and Anderson² prepared hydrogen telluride from aluminum telluride by the action of dilute hydrochloric acid, and, after being dried, the gas was condensed with liquid air and fractionally distilled. Each fraction was converted to metallic tellurium at a high temperature, and, after being weighed, was oxidized with nitric acid and the dioxide was weighed. The results varied irregularly, 31 out of 45 falling between 127.3 and 127.8. Another specimen of hydride resulted from the electrolysis of a phosphoric acid solution with tellurium cathodes. The fractions of this preparation were caught in nitric acid and after being weighed as the dioxide were dissolved and titrated with potassium permanganate. The average of thirty-seven results, from 22 fractions, between 127.76 and 127.36, is 127.50. The authors consider that there is no evidence of the existence of divi-tellurium.

THE DISSOCIATION OF HYDROGEN INTO ATOMS.

[PART II.]

CALCULATION OF THE DEGREE OF DISSOCIATION AND THE HEAT OF FORMATION.

BY IRVING LANGMUIR.

Received December 21, 1914.

The first part of this paper⁶ dealt with experiments on the heat losses from fine tungsten wires in hydrogen at pressures ranging from 0.010 mm. up to atmospheric pressure. The results were given in a series of tables, and form the basis for the present calculation of the degree of dissociation and the heat of formation of molecular hydrogen.

The previous calculations of the dissociation of hydrogen⁷ were based on the use of the equation

$$(3)^8 \quad W_D = SDq_1c_1$$

as described in Part I. The equation itself rests on a firm foundation, but the assumptions previously made in applying it to experimental results are open to serious criticism.

In the first place, it was assumed that the diffusion coefficient D could be calculated with sufficient accuracy from some equations of the kinetic

⁷ *Ibid.*, 34, 860 (1912). This paper will hereafter be referred to as the "paper of 1912."

⁸ For the derivation of this and some of the following equations, see Part I, or the "paper of 1912." The numbers of the equations are the same as those used in Part I.

theory by the rather arbitrary choice of a value for the mean free path of hydrogen atoms through ordinary molecular hydrogen.

Secondly, it was assumed that the shape factor S in the above equation had the same value as that obtained from the data on the convection losses in hydrogen at temperatures below that at which dissociation occurred.

Thirdly, it was assumed that the hydrogen in the immediate vicinity of the tungsten wire was in chemical equilibrium at a temperature corresponding to that of the wire. In other words, c_1 was taken to be the equilibrium concentration at the temperature of the wire.

And finally, the value of q_1 was found by a method which itself involved any error occurring in D .

Each of the four factors in Equation 3 was therefore liable to error. This was realized and pointed out at the time the calculations were made, but there was then no reason to suspect that any of these sources of error was serious enough to greatly affect the results.

In the present paper we shall endeavor to avoid these arbitrary assumptions and, by a careful analysis of the mechanism of the phenomena occurring in and around the wire, we will attempt to estimate and eliminate the errors which would otherwise occur.

1. Effect of Convection Currents.

In the experiments with hydrogen at atmospheric pressure the effect of convection currents in heating the upper part of the bulb was very noticeable. But in the bulbs with 200 mm. pressure of hydrogen or less, the upper part of the bulb was not as strongly heated as the lower part. It is, in fact, well known that convection currents decrease rapidly in intensity as the pressure is lowered, also that in hydrogen they are very much less pronounced than in other gases. If one considers the cause of convection currents it is evident that the behavior of hydrogen is just what one should expect.

The force producing convection currents is proportional to the difference in the densities of the ascending and descending currents of the gas. Since the density of a gas is equal to pM/RT it is readily seen that the force producing convection is thus proportional to

$$\frac{pM}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) = \frac{pM}{RT_1} \left(\frac{T_2 - T_1}{T_2} \right).$$

This force is directly proportional to the density of the gas and to the fraction $(T_2 - T_1)/T_2$. As T_2 becomes large this fraction approaches unity as a limit, so that, at very high temperatures, there is little tendency for convection to increase, and even this is largely counteracted by the increasing viscosity of the gas at high temperatures.

The experimental results themselves, however, furnish us with data by which we can estimate the effect of convection currents.

At temperatures below that at which perceptible dissociation of hydrogen occurs, we have seen that the heat losses from the filament are given fairly accurately by the equation (see Table III, Part I).

$$(2) \quad W_C = S(\varphi_2 - \varphi_1).$$

The shape factor S for concentric cylinders is equal to (*Phys. Rev.*, 34, 407 (1912))

$$(7) \quad S = \frac{2\pi}{\ln b/d}$$

where b is the diameter of the film of gas around the wire through which conduction takes place and d is the diameter of the wire.

Let us now substitute the experimentally determined values of S from Table III in this equation, together with the known value of d ($= 0.00706$ cm.) and solve the equation for b . We thus find

p .	S .	b .
750 mm.	1.25	1.08 cm.
200.	0.88	9.0
100	0.72	45.0
50	0.56	530.0

At atmospheric pressure the effective diameter of the film of conducting gas around the tungsten wire is about one centimeter, but at 200 mm. pressure the diameter is already 9 cm., which is larger than the diameter of the bulb (7 cm.). This means that the heat loss from the filament is actually less than if there were no convection currents and the ordinary laws of heat conduction could be applied. At lower pressures the heat loss becomes still less, although we know that the true heat conductivity of gases is independent of the pressure.

These considerations lead us to conclude that the effects of convection currents can be neglected even at pressures as high as 200 mm. We shall see that the decrease in the values of S at the lower pressures is due to a temperature discontinuity at the surface of the wire.

2. The Temperature-drop at the Surface of the Wire.

Kundt and Warburg,¹ in a study of the viscosity of gases at low pressures, showed, both experimentally and theoretically, that there is a certain apparent slipping of the gas along the surface. In gases at atmospheric pressure this effect is very small, but it varies inversely proportional to the pressure and thus becomes very important at low pressures. The thickness of the layer in which this slipping occurs is approximately equal to the mean free path of the gas molecules. Kundt and Warburg predicted, from the analogy between viscosity and heat conduction, that a corresponding discontinuity in temperature at the surface of a solid body

¹ *Pogg. Ann.*, 156, 177 (1875).

would be observed in the case of heat conduction through gases at low pressure.

Over twenty years later Smoluchowski¹ actually observed and studied this temperature drop and developed the theory of it. The temperature drop occurred within a layer about equal in thickness to the free path of the molecules. Smoluchowski found that in some gases, particularly hydrogen, the amount of heat given up to the gas by a solid body was only a fraction of that which should be delivered if each molecule striking the surface reached thermal equilibrium with the solid before leaving it.

Smoluchowski developed the theory of this effect along the lines of two alternative hypotheses, which he denotes by A and B.

Hypothesis A is equivalent to that made more recently by Knudsen.² It assumes, when molecules of a temperature T_1 strike a surface at a higher temperature T_2 , that the molecules leaving the surface have a temperature T which is intermediate between T_2 and T_1 and that the relation holds

$$(8) \quad T - T_1 = \alpha(T_2 - T_1)$$

where α is a number less than unity and is called by Knudsen the "accommodation coefficient."

Hypothesis B is similar to that originally used by Maxwell³ in dealing with the slip of gases. It assumes that, of all the molecules striking the surface, a fraction, f , reaches thermal equilibrium with it, while the fraction $1 - f$ is reflected without change of temperature (or rather velocity).

The two methods give analogous, but quantitatively slightly different results. Smoluchowski⁴ considers that the accuracy of experimental results has not yet been sufficient to distinguish between them, notwithstanding Knudsen's opinion to the contrary, and that in all probability the truth is intermediate between the two.

The formulas developed by Smoluchowski are only adapted to be applied to small differences of temperature and to heat conduction between surfaces whose radius of curvature is large compared to the mean free path of the molecules. In the present experiments, however, we are dealing with very small wires and with temperature drops of sometimes a thousand degrees or more, and we shall therefore need to derive the equations independently. We shall choose a simpler, although less rigorous method, based upon the same principles as those used by Smoluchowski. In this way we shall gain a clearer insight into the phenomena occurring around the wire and will be in a better position to apply similar principles to the problem of calculating the degree of dissociation of the gas.

Theory of Heat Conduction from Small Wires.—Let us consider a small heated wire A (Fig. 1) placed in the axis of a large cylindrical bulb B of diameter b , containing gas at such low pressure that the effects of convection can be neglected. Let T_s be the temperature of the wire and T_1 that of the bulb. If λ represents the length of the mean free path, then the distance which a molecule leaving the wire travels before colliding with other molecules is approximately λ .¹ On the other hand, the molecules striking the wire come from an average distance λ . Let us draw a circle, C (in Fig. 1), of diameter $d + 2\lambda$, around the wire, whose diameter is d and a similar circle D of diameter $b - 2\lambda$.

FIG. 1.

We may now look upon the heat conduction from the wire A to the cylinder B as taking place in the following steps:

1. Molecules of gas leave the wire and travel to C, where they are absorbed, and some molecules from C travel to the wire, a certain fraction of these absorbing heat from the wire.
2. From C to D the heat is carried according to the ordinary laws of heat conduction.
3. From D to B the energy is transferred by a simple interchange of molecules in a similar way to the transfer from A to C.

Thus we consider a temperature discontinuity from A to C and from D to B, but a continuous variation of temperature from C to D.

Since we are dealing with small wires in relatively large cylinders, we can readily see that the temperature drop from D to B will always be negligible compared to that from A to D. We shall therefore leave it out of consideration.

Let us represent by T_0 the temperature of the gas at C. We can now calculate the temperature drop $T_s - T_0$.²

If we let m be the rate at which the gas comes into contact with the

¹ Knudsen, *Ann. Phys.*, 34, 654 (1911), shows that the temperature of the molecules striking a plane surface corresponds to the temperature of the gas at a distance equal to 0.95 times the mean free path of the molecules. Using more recent data than that available to Knudsen, I calculate from his formulas that this coefficient should be about 1.2. Undoubtedly the coefficient would be somewhat different for very small wires from what it is for plane surfaces, but in any case its order of magnitude is close to unity. Fairly large errors in the value of this coefficient make only very slight differences in the results that are to be obtained by its aid.

² This is somewhat greater than the temperature drop defined by Smoluchowski, for it includes the *normal* temperature difference between A and C.

wire (in grams per sq. cm. per second), then the heat carried from the wire per second will be (per cm. of length)¹

$$(9) \quad W_C = 4.19 \pi d (C_v/M) \alpha (T_2 - T_a)m.$$

where W_C is the heat carried from the wire per unit volume and the coefficient α is the accommodation coefficient, and d is the diameter of the wire.

In order to calculate $T_2 - T_a$ from Equation 9 we must now substitute in it the value of m as given by Equation 5 of Part I, namely,

$$(5) \quad m = \sqrt{\frac{M}{2\pi RT_a}} p.$$

Here M is the molecular weight of the gas, T_a is the temperature of the gas at a distance λ from the wire (at C in Fig. 1).

In the derivation of this formula Maxwell's distribution law was assumed to hold. Where the temperature discontinuity at the surface is as large as in the present experiments the distribution of velocities among the molecules is undoubtedly very complex. The error involved in using this equation must, however, be relatively small.²

Before substituting (5) in (9) let us insert the numerical values of the constants. In (5) we place $M = 2$, $R = 8.32 \times 10^7$ ergs/° C. and express p in mm. of mercury and m in grams per sq. cm. per second. We thus obtain

$$(10) \quad m = \frac{0.0825 p}{\sqrt{T_a}}.$$

In (9) we place $C_v = 5.26$ g. cal. per degree (from 300° to 1500° K.)³ and $d = 0.00706$ cm. This gives, when we combine with (10)

$$(11) \quad T_2 - T_a = 49.6 \frac{W_C \sqrt{T_a}}{\alpha p}.$$

¹ Knudsen shows that this should be multiplied by 4/3, since the average velocity of all the molecules striking any surface is greater than the average velocity of the molecules in the body of the gas. This is due to the fact that the molecules of high velocity have a much greater chance of striking a surface than those of low velocity. On the other hand, for polyatomic gases the exchange of rotational energy is not complete and, therefore, a quantity less than should be substituted in the above equation. According to Smoluchowski, the combined effect of these two corrections would lead to a coefficient of 16/15 in place of the 4/3 mentioned above. For the present purpose this small correction may be neglected.

² With large differences of temperature over distances comparable with the free path, another effect, which we may call the radiometer effect, enters to render Equation 5 inaccurate. The rapidly moving molecules leaving the wire tend to drive back the slower incoming molecules and thus to decrease the rate at which the molecules strike the wire. Although this effect would be very important if we were dealing with large flat surfaces, calculation shows that in our present experiments, where only fine wires are employed, this error is always less than 5% and usually much less than this. It has, therefore, been neglected.

³ The letter K is used to denote temperatures on the absolute scale (Kelvin).

This equation enables us to estimate the difference between the temperature of the wire and that of the gas molecules which strike its surface.

We may also calculate the temperature of the gas molecules striking the wire in another way. Between the surface C (Fig. 1) and the bulb, the ordinary laws of heat conduction must apply at pressures below that at which convection occurs. Thus we may place, according to (2) and (7)

$$(12) \quad W_C = \frac{2\pi}{\ln b/(d + 2\lambda)} (\varphi_a - \varphi_1).$$

If we know the effective diameter of the bulb and the mean free path of the gas molecules, we can calculate from this equation the value of $(\varphi_a - \varphi_1)$, and since φ is a known function of the temperature, this in turn will enable us to determine T_a .

Let us now calculate T_a from our experiments with hydrogen by means of Equations 11 and 12. For this purpose we will choose the data obtained at 1500°K. , for at this temperature there is no appreciable dissociation and the temperature measurements are more accurate than at lower temperatures. These data, as taken from Tables I and II of Part I, are given below in Table V in the second column. The figures represent the watts per centimeter carried by the hydrogen from a wire at 1500°K. The first column gives the pressure of hydrogen in mm. of mercury. In the third column are the values of T_a calculated by Equation 11.

TABLE V.--WIRE IN HYDROGEN.

$T_2 = 1500.$			$\alpha = 0.19.$			
1. $p.$	2. $W_C.$	3. T_a by (11).	4. λ cm.	5. $\varphi_a - \varphi_1.$	6. $b.$	7. T_a by (12).
750	5.50	1428	0.0001	[4.10]	0.78	(1428)
200	3.90	1316	0.0003	[3.53]	1.87	(1316)
100	3.13	1216	0.0006	[3.03]	3.7	(1216)
50	(2.52)	1071	0.0011	2.39	[3.7]	1070
25	1.92	900	0.0020	1.78	[3.7]	920
10	(0.94)	806	0.0037	0.83	[3.7]	660
4.4	0.47	742	0.0063	0.46	[9.0]	520
1.1	0.19	495	0.020	0.16	[9.0]	390
0.207	0.050	341	0.094	0.03	[9.0]	317
0.039	0.009	360	0.5	0.003	[9.0]	302
0.015	0.004	[300]	1.3	0.001	[9.0]	300

The accommodation coefficient α was calculated from the data at the lowest pressure (0.015 mm.) by substituting $T_a = 300$;¹ $T_2 = 1500$; $W_C = 0.004$; and $p = 0.015$ in Equation 11. This gave $\alpha = 0.19$, which, when substituted in (11) gave

$$(13) \quad T_2 - T_a = 260 (W_C/p) \sqrt{T_a}.$$

¹ That it is justifiable to place $T_a = 300$ at these lowest pressures is shown by the results obtained below and given in the seventh column.

The values of T_a given in the third column of Table V were obtained by solving these quadratic equations.

The free path of hydrogen molecules at 0° C. and 1 mm. pressure is 0.0135 cm., according to O. E. Meyer. The free path varies with the temperature according to Sutherland's formula, but for the present purpose it is accurate enough to assume that it is inversely proportional to the density. The fact that at low pressures the molecules leaving the surface at a much lower temperature than the surface temperature makes the calculation of the free path leading to the formula

$$(14) \quad \lambda = \frac{10.5 \times 10^{-6}}{p} \sqrt{\frac{2T_2}{T_2 + T_a}}$$

This equation was used to calculate the free paths given in Col. 4 of Table V.

At the higher pressures the effects of convection currents cannot be neglected, so that Equation 12 would not be expected to hold accurately under these conditions. However, even in the case of convection from small wires in the open air we may profitably look upon the phenomena as consisting essentially in conduction through a film of stationary gas of a certain thickness. If we adopt this view-point, Equation 12 applies even at the higher pressures, but b then no longer represents the diameter of the bulb, but becomes the effective diameter of the film of gas through which conduction occurs. To determine the value of b we need only substitute the values of W_C , d , λ and $\varphi_a - \varphi_1$ in Equation 12 and solve for b . For this purpose the values of $\varphi_a - \varphi_1$ were calculated from T_a , for the pressures of 760 to 100 mm., and are given in Table V (Col. 5) in brackets. These then served to calculate b from (12). At the lower pressures (50–10 mm.) it was then assumed that convection currents were absent and that b was therefore independent of the pressure and equal to the value 3.7 cm., as found at 100 mm. Below 10 mm. b was placed equal to the diameter of the bulb, for in these experiments a straight wire in a cylindrical bulb was used.

The values of $\varphi_a - \varphi_1$ at the lower pressures were obtained from (12) by substituting in it W_C , b , d and λ as given in the table. The results are given in Col. 5 (without brackets) and were used to calculate the corresponding values of T_a given in the seventh column.

By comparison of Cols. 3 and 7, it is seen that there is reasonably good agreement between the values of T_a calculated by these entirely independent methods. The fact that the temperature drop at the surface of the wire ($T_2 - T_a$) is so large, even at the higher pressures, is the reason

¹ Derived from the equations given on page 260 of Meyer's "Kinetische Theorie der Gase," German edition of 1899.

for the variation of the shape factor (given in Table III at the heads of the columns).

The accommodation coefficients α is found above to be equal to 0.19. This is considerably lower than the value 0.36 found by Knudsen for hydrogen in contact with polished platinum at approximately room temperature.

The results given in Col. 6 of Table V show that the effective thickness of the layer of "stationary" gas around the wire increases as the pressure decreases from 750 to 100 mm., owing to convection currents. At lower pressures, however, the results indicate that there is no further change in b . If the lamps used in these experiments had contained a long, straight filament in the axis of a cylindrical bulb, then b should be equal to the diameter of the bulb. Actually, however, the filament was a short loop only about 3 cm. long. The resulting divergence of the lines of heat flow would tend to increase the shape factor, which would be equivalent to a decrease in diameter of a cylindrical bulb. Hence the value of 3.7 cm. found above for b is in as close agreement with the actual bulb diameter (7 cm.) as the experimental conditions would seem to warrant.

Nitrogen.—Similar calculations from the data given in Table I, for a filament at a temperature of 2400° in nitrogen yield the results shown in Table VI. The values of T_a in Col. 3 were obtained from a formula similar to (11) in which, however, the coefficient 49.6 was replaced by 166, corresponding to the different molecular weight and specific heat of nitrogen. The columns of Table VI correspond exactly to those of Table V.

It is seen by the variation of b that the effect of convection is much more marked than with hydrogen and persists at pressures even as low as 50 mm.

TABLE VI.—WIRE IN NITROGEN.

$T_f = 2400.$					$\alpha = 0.60.$	
1. $p.$	2. WC.	3. $T_a.$	4. λ cm.	5. $\varphi_a - \varphi_1.$	6. $b.$	7. T_a by (12).
750	2.46	2356	0.0001	[1.68]	0.54	(2356)
200	2.06	2264	0.0003	[1.56]	0.89	(2264)
100	1.87	2160	0.0006	[1.44]	1.01	(2160)

10	0.75	1580	0.0046	0.74	[8]	1530
1	0.16	1000	0.031	0.12	[8]	650

The accommodation coefficient is much larger than that of hydrogen, but is again less than that given by Knudsen (for air) at room temperature.

The agreement between the values of T_a calculated by the two independent methods, in both Tables V and VI, is sufficiently good to show that the general theory of heat conduction and convection used in making the calculations can safely be applied to the case of fine tungsten wires in hydrogen and nitrogen at all pressures. Evidently the heat conductivities

of these gases, within the ranges of temperature considered above, vary with the temperature in the way that is to be expected from their behavior at ordinary temperatures.

3. Concentration Drop at the Surface of the Wire.

We have seen that the temperature of the layer of gas next to the wire may be very much lower than that of the wire itself. To assume that these two temperatures are equal, which amounts to assuming temperature equilibrium at the surface of the wire, would lead to entirely erroneous results.

The diffusion of one gas through another is a phenomenon closely related to heat conduction. In the case of the evaporation of a solid surrounded by a gas, where the vapor must diffuse outward through the gas, the partial pressure of the vapor at the surface of the solid will be less than that of the saturated vapor. In other words, there will be a "concentration-drop" at the surface, just as there is a "temperature drop" in the analogous case of heat conduction, and a "slip" in gases where viscosity effects are involved. Analogy suggests that this concentration drop will be inversely proportional to the pressure.

In the previous calculations of the dissociation of hydrogen it was assumed that the concentration of the hydrogen atoms close to the wire, was that corresponding to equilibrium at the temperature of the wire. As the experiments underlying these calculations were made at atmospheric pressure, this assumption involved no serious error, but at the low pressures which we are now to consider, such an assumption would render the results worthless.

In analyzing the effect of the surface concentration drop in our present experiments, we may follow methods entirely analogous to those which we adopted in estimating the temperature drop.

Let us consider the mechanism of the phenomena occurring on and around a tungsten wire surrounded by hydrogen, and heated to such a high temperature that the hydrogen is partly dissociated. The hydrogen molecules striking the surface come from an average distance of approximately λ (the mean free path). A certain proportion of these molecules leave the surface without change (reflected) and another portion is absorbed by the wire and may thus be dissociated. Similarly, hydrogen atoms striking the filament may be absorbed or reflected. The hydrogen which is absorbed probably reaches chemical equilibrium within the wire and the atoms and molecules in certain proportions diffuse out and away from the wire. We assume that the hydrogen not absorbed undergoes no chemical change.

Let m_2 represent the rate at which hydrogen molecules strike the surface of the filament (in grams per sq. cm. per second) and m_1 be the corresponding rate for the hydrogen atoms. Let $\alpha_1 m_1$ be the rate at which the hydrogen atoms are absorbed by the wire and $\alpha_2 m_2$ be the rate at which the

molecules are absorbed. Now in a stationary condition the total amount of hydrogen escaping from within the wire must be equal to the rate at which it is absorbed. We may look upon the surface of the wire as the boundary of a space containing hydrogen in equilibrium. The rate at which the hydrogen atoms in the metal reach the surface (from within) we shall call n_1 , and the corresponding rate for the molecules n_2 . Similarly, we shall let $\beta_1 n_1$ be the rate at which atoms escape from the metal and $\beta_2 n_2$ the rate at which molecules escape. Then in a stationary state we have

$$(15) \quad \beta_1 n_1 + \beta_2 n_2 = \alpha_1 m_1 + \alpha_2 m_2.$$

We assume that the coefficients α and β are constant; that is, that they are independent of m and n , although they may vary with the temperature.

The energy (watts) carried away from the wire (per cm.) because of the dissociation, we have called W_D . If q_1 be the heat (calories) necessary to dissociate 1 g. of hydrogen, then we have

$$(16) \quad W_D = 4.19 \pi d q_1 (\alpha_2 m_2 - \beta_2 n_2).$$

Here d is the diameter of the wire. The quantity in parenthesis is the difference between the rates at which hydrogen molecules are absorbed and are given up by the wire and therefore is equal to the rate at which hydrogen is dissociated.

If we place

$$(17) \quad \omega = W / (4.19 \pi d q_1)$$

then (16) becomes

$$(18) \quad \omega = \alpha_2 m_2 - \beta_2 n_2$$

Combining this with (15), we obtain

$$(19) \quad \omega = \beta_1 n_1 - \alpha_1 m_1$$

whence

$$(20) \quad \begin{cases} \beta_1 n_1 = \alpha_1 m_1 + \omega \\ \beta_2 n_2 = \alpha_2 m_2 - \omega \end{cases}$$

Now we have assumed that equilibrium exists between the hydrogen atoms and molecules absorbed by the wire. According to the law of mass action, the concentration of the hydrogen molecules in the metal is proportional to the square of the concentration of the atoms. But n_2 and n_1 must be proportional to these concentrations. From Equation 20 we thus obtain

$$(21) \quad (\alpha_1 m_1 + \omega)^2 = A(\alpha_2 m_2 - \omega).$$

Here A is a constant which is proportional to the dissociation constant of hydrogen dissolved in the metal. We may now obtain a relation between this quantity A and the true dissociation constant K of gaseous hydrogen (outside the wire).

We have

$$(22) \quad K = (p_1')^2 / p_2'$$

where p'_1 and p'_2 are, respectively, the partial pressures of hydrogen atoms and molecules corresponding to equilibrium in the gaseous phase.

By Equation 5 (Part I) we have from (22) by placing $M_1 = 1$ and $M_2 = 2$

$$(23) \quad K = \sqrt{4\pi RT_2} (m'_1)^2 / m'_2$$

where T_2 is the temperature of the filament.

On the other hand, if we place $\omega = 0$ in (21), we obtain the condition for equilibrium. In this case (21) becomes

$$(24) \quad A = (\alpha'_1 / \alpha_2) \cdot (m'_1)^2 / m'_2$$

and by combining this with (23) we find the desired relation between A and K

$$(25) \quad K = \sqrt{4\pi RT_2} (\alpha_2 / \alpha'_1) A.$$

If we now substitute in (21) the values of m_1 and m_2 from Equation 5 and then combine with (25), we obtain

$$(26) \quad K = \sqrt{T_2 / T_a} \frac{(p_1 + \omega \sqrt{2\pi RT_a} / \alpha_1)^2}{p_2 - \omega \sqrt{2\pi RT_a} / \alpha_2 \sqrt{2}}.$$

Here T_a is the temperature of the gas around the wire at a distance λ from it (corresponding to circle C of Fig. 1). When $\omega = 0$ and $T_a = T_2$ this equation reduces to the ordinary form of the law of mass action. The "drop in concentration" corresponding to the drop in temperature previously considered is equivalent to $\omega \sqrt{2\pi RT_a} / \alpha_1$.¹

In the above equation p_1 and p_2 are the partial pressures of hydrogen atoms and molecules at a distance λ from the wire.

Let us substitute the numerical values of the constants involved in (26). If we express p in mm. of mercury, then the factor $\sqrt{2\pi R}$ is 17.15. If we place $d = 0.00706$ cm. (the diameter of the wire) in (17) we find $\omega = 10.8 W_D / q_1$. Substituting these in (26), we obtain

$$(27) \quad K = \sqrt{T_2 / T_a} \frac{(p_1 + 185 W_D \sqrt{T_a} / \alpha_1 q_1)^2}{p_2 - 131 W_D \sqrt{T_a} / \alpha_2 q_1}.$$

Here p is expressed in mm., W_D in watts per cm., and q_1 in calories per gram.

4. Diffusion of Atomic Hydrogen away from the Wire.

In the calculation of the temperature drop around a wire in hydrogen, we used two methods which led to Equations 11 and 12, respectively. Similarly, in the calculation of the concentration drop, two methods may be used. The method adopted above in obtaining Equation 27 is analogous to that used in deriving (11), whereas the following method corresponds to that employed in obtaining (12).

In the "paper of 1912" it was shown that

$$(3) \quad W_D = S D q_1 c_1$$

¹ Expressed as partial pressure instead of concentration.

Here c_1 is to be expressed in mols per cc., and is equal to

$$(28) \quad c_1 = p_1/RT.$$

The diffusion coefficient varies with the temperature according to Sutherland's formula, but at the high temperatures we are dealing with, this becomes equivalent to stating that the diffusion coefficient varies with the $3/2$ power of the temperature. We will assume that the diffusion coefficient of hydrogen atoms through molecular hydrogen varies in this way with the temperature, although we shall avoid assumptions as to its actual magnitude. Since the diffusion coefficient is inversely proportional to the pressure, we may thus place:

$$(29) \quad D = D_0 (T_a/273)^{3/2} (.760/P)$$

where D_0 is the diffusion coefficient at 0° and 760 mm. pressure, and T_a is the temperature of the gas around the wire (*i. e.*, at the distance λ from it).

Combining (29), (28), and (3) we obtain, after substituting the numerical value for R

$$(30) \quad W_D = 11.3 \times 10^{-6} S q_1 D_0 \sqrt{T_a} p_1/P.$$

This equation gives us the desired relation between p_1 , the partial pressure of hydrogen atoms around the wire, and W_D . It enables us to calculate the degree of dissociation if we know S , q_1 and D_0 .

5. Equations Involved in Calculating the Dissociation Constant, etc.

Equation 27 has given us a means of calculating the dissociation constant from the partial pressures of hydrogen atoms and molecules around the wire. These partial pressures may be expressed in terms of the diffusion constant by means of Equation 30. By combining these two equations it is possible to obtain a general solution of the problem in the following form:

$$(31) \quad K = \sqrt{T_2/T_a} \frac{W_D^2 (BP + E)^2}{P - W_D (BP + C)}$$

where

$$(32) \quad B = 88500/(SD_0 q_1 \sqrt{T_a}) \text{ cm. per watt}$$

$$(33) \quad C = 131 \sqrt{T_a}/(\alpha_2 q_1) \text{ mm. of Hg per watt/cm.}$$

$$(34) \quad E = 185 \sqrt{T_a}/(\alpha_1 q_1) \text{ mm. of Hg per watt/cm.}$$

The dissociation constant K increases rapidly with the temperature, while B , C and E depend only to a small degree on the temperature, and therefore we see by (31) that at low temperatures W_D will increase approximately proportional to \sqrt{K} . At high temperatures, however, the two terms in the denominator must tend to become equal, so that W_D would approach a limiting value. From Equation 31 we can readily derive simple equations for these limiting cases.

At low temperatures the second term of the denominator is negligible, so that

$$(35) \quad K = \sqrt{T_2/T_a} \ W_D^2 (BP + E)^2/P.$$

At low pressures this gives:

$$(36) \quad W_D = \sqrt[4]{T_a/T_2} \ \sqrt{PK/E}.$$

At high pressures (here $T_a = T_2$).

$$(37) \quad W_D = \sqrt{K/P/B}.$$

At intermediate pressures W_D increases to a maximum. Differentiating (35) with respect to P and placing $dW_D/dP = 0$ leads to following maximum value of W_D (here $T_a = T_2$):

$$(38) \quad W_{\max.} = \sqrt{K/4BE}.$$

The pressure at which this maximum occurs is

$$(39) \quad P' = E/B.$$

At high temperatures W_D increases so that ultimately $W_D(BP + C)$ becomes nearly equal to P . Beyond this value it cannot go. Therefore, at high temperatures W_D must gradually approach a limiting value. This limit is

$$(40) \quad \begin{array}{l} \text{at low pressures} \\ W_D = P/C \end{array}$$

$$(41) \quad \begin{array}{l} \text{at high pressures} \\ W_D = 1/B. \end{array}$$

The higher the pressure the higher is the temperature at which W_D approaches its limiting value.

We shall see that the case where $C = E$, is of special importance. If we make this substitution in (31) and place

$$(42) \quad F = BP + E$$

we obtain the very simple equation

$$(43) \quad K = \sqrt{T_2/T_a} \ \frac{F^2 W_D^2}{P - F W_D}.$$

At higher pressures T_a becomes practically equal to T_2 , so the equation is still further simplified.

$$(43a) \quad K = F^2 W_D^2 / (P - F W_D).$$

Comparing this with (22), we see that $F W_D$ is equal to the partial pressure of hydrogen atoms corresponding to equilibrium at the temperature of the filament. The degree of dissociation of the hydrogen in equilibrium is therefore $F W_D / P$.

At low temperatures we have already found expressions for the maximum value of W_D and the pressure at which this occurs. On the assumption that $C = E$ we may now find more general expressions applicable even

at high temperatures. Differentiating (42) and (43a) with respect to P , placing $dW_D/dP = 0$ and solving the resulting equation together with (31), we obtain

$$(44) \quad W_{\max.} = 1/(B + \sqrt{4BE/K}).$$

$$(45) \quad P' = (E/B) + \sqrt{EK/B}.$$

6. Calculation of Results from Experimental Data.

The equations that have been derived in the preceding section give us means of calculating the coefficients B , C and E , and in this way of determining the dissociation constant K . Thus from the experiments at low pressures and at low temperatures it should be possible by (36) to find the ratio $\sqrt{K} : E$. Experiments at high pressures give by (37) $\sqrt{K} : B$, while those at high temperatures and low pressures give C according to (40). At high pressures and high temperatures we should then obtain B by (41). By combining these results it would thus be possible to find the actual values of B , C , E and K , separately. In practice, however, this method gives difficulty, because the experiments do not cover a sufficiently wide range of pressures or temperatures to allow these limiting equations to hold accurately. Furthermore, the values of W_D obtained under the extremes of temperature or pressure are often subject to unusually large experimental error, and it is unwise to use such data exclusively for the determination of the coefficients. A third difficulty is that Equations 36, 37, 40 and 41 all involve to some extent T_a , the temperature of the gas around the wire, which is not accurately known.

The method finally adopted to determine the coefficients B , C and F has been chosen because of its relative freedom from these difficulties.

1. The Value of C .—According to our theory, at very low pressures, W_D does not increase indefinitely with rising temperature, but approaches a limiting value equal to P/C (Equation 40). If we examine the experimental data of Table III we see, in fact, that W_D at the three lower pressures, 0.015, 0.039 and 207 mm., becomes constant at temperatures over 2700° . This is also readily seen from Fig. 2, in which $\log W_D$ has been plotted against $1/T$. The limiting value of W_D at high temperatures for each of these pressures is given in the following table, along with the ratio P/W_D , which, according to (40), is equal to C :

TABLE VII.

P .	W_D .	$C = P/W_D$.	T_a .
0.015	0.18	0.0835	300
0.039	0.47	0.083	300
* 0.207	1.85	0.112	545

The constancy of C at the lower pressures and its increase at the higher pressure, is in full accord with Equation 33, which states that C is proportional to $\sqrt{T_a}$. At very low pressures T_a must be equal to the tempera-

ture of the bulb (300° K.), just as it was at lower filament temperatures (see Table V). At higher pressures, however, where the hydrogen atoms recombine long before reaching the surface of the bulb, the heat evolved raises the temperature of the gas considerably. At the lower pressures, however, we may safely place $T_a = 300$, and we then find, by comparing Table VII with Equation 33:

$$(46) \quad C = 0.0048 \sqrt{T_a}$$

$$(47) \quad \alpha_2 q_1 = 27300$$

This indicates, since by definition α_2 cannot exceed unity, that q_1 must be greater than 27300, or the heat of formation of 2 g. of hydrogen molecules, must be greater than 54600 calories.

If we compare (46) with the value $C = 0.112$ obtained for $P = 0.207$, we find $T_a = 545$. This is, as we shall see later, an entirely reasonable value.

2. Calculation of an Approximate Value of q_1 .—If we can determine q_1 , then by (47) we can calculate α_2 . This will, in a certain measure, give us a check on our theory, for we know that α_2 cannot exceed unity.

To calculate q_1 , we may make use of van't Hoff's equation

$$(48) \quad d \ln K / dT = q / RT^2.$$

Here q is the heat of reaction at constant pressure since K is expressed in terms of partial pressures. The relation between q and q_1 is

$$(49) \quad q = 2q_1 + RT.$$

If we use ordinary logarithms in place of naperian and substitute $R = 1.98$ calories, we may write Equation 48 as follows:

$$(50) \quad d \log K / d(1/T) = -q / 4.57$$

Since q varies so little with the temperature, we should, according to (50), obtain practically a straight line if we plot $\log K$ against $1/T$. The slope of the line would then be $q/4.57$, from which, by (49), we could calculate q_1 . The slope of this line, however, would be the same if we plot the logarithm of any quantity proportional to K , instead of the logarithm of K itself. If we could assume that $T_a = T_2$ and that B and E were independent of the temperature, then we see from (35) that W_D^2 should be proportional to K . The values of q_1 that we might thus obtain by plotting $\log W_D^2$ would not be very accurate, because the above assumptions are not strictly correct. However, by using Equation 38, which gives us a relation between K and W_{\max} , we avoid these difficulties. By (32) and (34) we see that the factor BE is independent of T_a and T_2 , so that K is strictly proportional to W_{\max} . Another important advantage in using this equation in determining q is that it does not involve a knowledge of the pressure within the bulb. It should be remembered that in the experiments at pressures of 10 mm., and above, the pressures

of the hydrogen as given in Table III were not measured while the filaments were heated, but were the pressures at which the bulbs were sealed at room temperature. The actual pressures in the bulbs during the experiment must have been considerably higher.¹

It is clear, however, that this uncertainty in the pressure does not affect $W_{\max.}$ nor the accuracy of K calculated from it by (38).

By examining Table III we see, as the pressure increases, that W_D increases to a maximum and then decreases. In the following table are the maximum values of W_D corresponding to various temperatures as given in Table III:

TABLE VIII.

T.	$W_{\max.} = \sqrt{K/4BE.}$	T.	$W_{\max.} = \sqrt{K/4BE.}$
2000	1.3	2500	12.5
2100	2.4	2600	16.7
2200	4.0	2700	22.7
2300	6.1	2800	30.0
2400	8.9		

By plotting $2 \log W_{\max.}$ against $1/T$ we obtain in fact an almost perfectly straight line. From the slope of this line we calculate by (50) that $q = 85500$ calories. If we take $T_2 = 2400$ (the center of the range of temperatures in the experiments), we then find by (49)

$$(51) \quad q_1 = 40300 \text{ calories.}$$

3. Calculation of α_2 and Lower Limit for E .—Substituting (51) in (47), we obtain

$$(52) \quad \alpha_2 = 0.68.$$

This means that 68% of all the hydrogen molecules which strike the filament at high temperatures are absorbed by the filament.

If we substitute (51) in (34), we obtain

$$(53) \quad E = 0.0046 \sqrt{T_a}/\alpha_1.$$

Since α_1 cannot exceed unity, E must be greater than $0.0046 \sqrt{T_a}$.

The coefficient α_1 gives the fraction of the hydrogen atoms striking the filament which dissolve in it or are absorbed by it. There is a strong probability that this fraction should be very close to unity, for there is every reason to think that hydrogen atoms would be absorbed by a metal surface much more readily than the molecules, and we have just seen that 68% of the latter are absorbed. We shall see, however, that there is another way of estimating the value of α_1 .

4. Upper Limit for B .—According to (41), the limit which W_D approaches at high temperatures does not increase indefinitely with the pressure,

¹ In some of the experiments at a pressure of 100 mm. of hydrogen, the bulbs became so hot at the higher filament temperatures that the glass softened and sucked in slightly. In another experiment the bulb was immersed in water to keep it cool. This cooling did not have any perceptible effect on the value of W_D .

but ultimately becomes equal to $1/B$. By examining the results given in Table III for the higher pressures we see that W_D does not become constant even at the highest temperatures. This merely indicates that $1/B$ must be considerably greater than 117, the highest value of W_D observed. Or in other words, B must be less and probably much less than $1/117$, or 0.008.

5. Estimation of Ratio $E:B$.—According to (39) at low filament temperatures the fraction E/B should be equal to the pressure at which the maximum values of W_D occur. By referring to Table III we see that the highest values of W_D are observed at 50 mm. pressure. At the lower temperatures there is evidence that the maximum should lie at a pressure rather lower than 50 mm., although above 25 mm. The lack of experimental data at intermediate pressures makes it impossible to determine this pressure with much accuracy, but, making allowance for the heating of the gases in the bulb, it is probable that the true pressure at which the maximum W_D would occur is approximately 50 mm. From this we may conclude that $E/B = 50$.

6. Most Probable Values of E and α_1 .—Since B must be considerably less than 0.008 and E/B is equal to 50, we may conclude that E must be considerably smaller than 50×0.008 or 0.40. We have already seen that E must be greater than $0.0046 \sqrt{T_a}$. If we take $T_a = 2500$, E would have to be greater than 0.23. Therefore, E must lie between the comparatively narrow limits 0.23 and 0.40. There is, however, no reason for thinking that E must be greater than the lower limit, whereas there is evidence that it is considerably less than the upper limit. The most probable value of E is therefore obtained by placing $\alpha_1 = 1$ in (53). The value thus obtained is, however, almost identical with the value of C given by (46). We have seen from (43) that the mathematical treatment is much simplified if $C = E$. The small difference between 0.0048 and 0.0046 is well within the experimental error, so that for convenience we may place

$$(54) \quad C = E = 0.0048 \sqrt{T_a}.$$

7. Calculation of K from Low Pressure Data.

By the aid of these values of C and E we may calculate K from (43). We have seen that at high temperatures B is less than 0.008. Taking Equation 32 into consideration, we may thus conclude that B must always be less than $0.47/\sqrt{T_a}$. At very low pressures $T_a = 300$, so that under these conditions B might be as large as 0.027. At similarly low pressures $E = 0.083$. At a pressure $P = 0.207$ the term BP in (42) is less than 0.005 and may be neglected as compared to E in calculating F . We may thus calculate K from (43) without knowing the value of B , provided we use the data at pressures of 0.207 mm. and lower.

Table IX gives the results of such calculations from the data at the

lowest pressures. The values of K were calculated from the corresponding values of W_D by Equation 43, placing $F = E$. At 0.015 and 0.039 mm. pressure, T_a was placed equal to 300° , but at 0.207 mm. the values of T_a used in the calculation were those given in the next to the last column of the table.

TABLE IX.—DISSOCIATION CONSTANT OF HYDROGEN FROM LOW PRESSURE DATA.

2800	0.180	0.47	1.85	540
2900	0.180	0.47	1.85	540

The choice of $T_a = 300$, at the lowest pressures and the tabulated values at 0.207 mm., was based upon calculations similar to those previously employed in obtaining the temperature drop around a wire at low pressures. Thus we may calculate $\varphi_a - \varphi_1$ according to (12), substituting, however, $W_C + W_D$ in place of W_C . The data for the calculation, together with the results, are given in Table X. The values of $W_C + W_D$ were

TABLE X.

1.1	0.018	1.2
4.4	0.004	1.0

taken directly from Table II. In this calculation it is assumed that the hydrogen atoms leaving the filament all recombine to form molecules within a distance λ from the filament and that the heat thus liberated is carried to the bulb by ordinary heat conduction. This assumption, of course, cannot correspond exactly with the facts, but would lead to too high a value for T_a . It is therefore not surprising that the value $T_a = 760$ found at 0.207 mm. should be higher than the value $T_a = 545$ previously calculated by Equation 46 from the data of Table VII. Taking the value $T_a = 545$ as being correct and making a proportionate change in the corresponding values of $\varphi_a - \varphi_1$, we obtain the values of T_a given in Table IX. At the lower pressures the values of T_a are so close to 300° that it

is not worth while to take into account the departures from this temperature.

Before discussing the values of K of Table IX, we shall first attempt to calculate K from the data at pressures of 1.1 and 4.4 mm.

At these higher pressures there is more uncertainty as to the value that should be assigned to T_a . We may, however, adopt a method similar to that we employed to calculate T_a at a pressure of 0.207 mm. In the latter case at very high temperatures W_D became independent of T showing that the denominator in Equation 31 was practically zero. This led to Equation 40, from which we determined C and then by (33) we solved for T_a . At the pressures above 0.207 mm., however, W_D does not reach a constant value at the highest temperatures, although it shows a distinct tendency to do so. This is readily seen from Fig. 2, where $\log W_D$ has been plotted against $1/T$ for the data at pressures up to 4.4 mm. At the three lower pressures the curve becomes horizontal at the highest temperatures, but at 1.1 mm. the temperatures reached were not high enough to give the maximum value of W_D . From the degree of curvature or the change of slope, we may, however, estimate the value of C and in this way find T_a .

By substituting the value of K from (43) in the modified form of van't Hoff's Equation 50 and carrying out the indicated operations, we obtain (considering F as constant and $T_a = T_2$)

$$(55) \quad \frac{2d \ln W_D}{d(1/T)} + \frac{F dW_D/d(1/T)}{P - FW_D} = -\frac{q}{R}.$$

If we let $-U$ be the slope of the curve obtained by plotting $\log W_D$ against $1/T$, then the first term of this equation becomes equal to $-2 \times 2.30 U$ and in the second term we find $dW_D/d(1/T) = -2.30 U W_D$. Substituting these values in the equation and solving for U we find (since $R = 1.98$)

$$(56) \quad U = \frac{q}{4.57} \left(\frac{P - FW_D}{2P - FW_D} \right).$$

At lower temperatures FW_D becomes negligibly small compared to P , so that U approaches a definite limit U_0 which is equal to $0.109 q$. From this relation we can eliminate q from (56) and then solve for F , with the result:

$$(57) \quad F = \frac{P}{W_D} \cdot \frac{U_0 - U}{U_0 - \frac{1}{2}U}.$$

From the curve of Fig. 2 we find the slope of the curve at 2700° ($1/T = 0.000370$) to be 3760. We have already calculated that q is approximately 85000 and from this we obtain $U_0 = 0.109$, $q = 9300$. Substituting these in (57), together with W_D (at 2700°) = 5.7 and $P = 1.1$, we obtain

$$F = 0.145.$$

According to (42) $F = BP + E$. The term BP is very small compared to E . We shall see that $B = 0.23/\sqrt{T_a}$ and have already found $E = 0.0048 \sqrt{T_a}$. Substituting these values of B , E and F in (42) and solving for T_a , we find $T_a = 810$. From this we may now calculate T_a at all other filament temperatures, as we did at the lower pressures. Thus, taking $S = 1.2$ from Table X, we calculate $\varphi_a - \varphi_1$ from the corresponding values of W in Table II. If we use these values of $\varphi_a - \varphi_1$ we obtain temperatures for T_a that are much too high. However, by empirically taking $0.26 (\varphi_a - \varphi_1)$ we find, at a filament temperature of 2700° , the value $T_a = 810$ in agreement with the calculation above. The values of T_a for other filament temperatures are obtained from the corresponding values of $0.26 (\varphi_a - \varphi_1)$. The results are recorded in Table XI.

Having thus determined T_a , it is easy to find F at other temperatures by Equations 42, 54 and the relation $B = 0.23/\sqrt{T_a}$. These results are given in the fourth column of Table XI. The values of K given in the fifth column were obtained from F and W_D by (43).

The results shown in Table XII were obtained by exactly similar methods from the data of the experiments at a pressure of 4.4 mm.

8. Final Results for the Dissociation Constant K , and the Heat of Formation q_2 .

From the experiments at low pressures we have been able to calculate the numerical value of C and E and obtain preliminary estimates of B and q . From the experiments at each of the pressures up to 4.4 mm. we have calculated the dissociation constant K at temperatures from 1800 to 2900° and have collected the results in Tables IX, XI and XII. We are now in a position to test out the correctness of the theory which has been developed in this paper. The conditions which should be fulfilled by the values of K are

1. K should be independent of the pressure.
2. K should vary with the temperature according to van't Hoff's equation; that is, $\log K$ plotted against $1/T$ should give a straight line. The slope of this line determines the value of q .
3. The value of q thus found should agree with that obtained at higher pressures.

We see by examination of the tables that the values of K , found at the three higher pressures 0.207, 1.1 and 4.4 mm. are in excellent agreement. At 0.039 mm. the agreement is also good at the higher temperatures, but poorer at the lower temperatures. The results at 0.015 mm. are considerably lower than the others. On the whole, however, considering that these experiments extend over a range of pressures of nearly 300-fold, the agreement between the different values of K is surprisingly good.

FIG. 2
EXPERIMENTS AT LOW PRESSURES

At the lowest pressures the correction for radiation from the filament is so large that errors from this cause, particularly at the lower temperatures, may perhaps account for the observed variation in K .

In Fig. 3 the values of $\log K$ have been plotted against $1/T$. In order to prevent the curves from overlapping, the successive curves have been displaced vertically by one unit; thus $\log K$ is plotted for $P = 0.015$ mm., while $(1 + \log K)$ has been plotted for $P = 0.039$ and $(2 + \log K)$ for

$P = 0.207$, etc. The curves should be parallel and equidistant straight lines. The fact that they are actually so very nearly straight and parallel is excellent evidence of the correctness of the theory, especially so, since the curves obtained by plotting W_D in a similar way (see Fig. 2) are by no means straight.

Before proceeding further we will now examine the data and choose the most probable values of q to be used in subsequent calculations.

The slope of the lines in Fig. 3 enables us to calculate q by Equation 50. The results thus obtained are given in Table XIII.

TABLE XIII.

q = Heat of Formation of Hydrogen at Constant Pressure.

Pressure.....	0.015	0.039	0.207	1.1	4.4
q	108,000	96,000	91,500	100,000	97,000

We may also determine q from the experiments at higher pressures. For this purpose we may combine Equations 50 and 43. The difficulty arises that F is not strictly independent of the temperature, but varies

with it slightly and to an extent that depends on the relative magnitude of B and E (see Equation 42). Since the variation of F with the temperature is small compared with that of W_D , we may proceed as follows in calculating q :

At the higher pressures now being considered, we may safely place $\sqrt{T/T_1} = 1$ in Equation 43. We shall also see that under the conditions of our experiments at higher pressures the term FW_D in the denominator of (43) can be neglected in comparison with P .

Equation 43 thus simplifies to

$$(58) \quad K = F^2 W_D^2 / P.$$

If we substitute this value of K in (50) and carry out the indicated operations, we obtain

$$(59) \quad \frac{2d \log W_D}{d(1/T)} + \frac{2d \log F}{d(1/T)} = - \frac{q}{4.57}.$$

Now it can be readily shown by taking into account Equations 42, 32 and 34 that

$$(60) \quad \frac{2d \log F}{d(1/T)} = \frac{T}{2.30} \frac{PB - E}{PB + E}.$$

This term is in the nature of a correction term. The first term of (59) is obtained directly by plotting $\log W_D$ against $1/T$. To calculate q we may therefore transform (59) to the following:

$$(61) \quad q = -9.14 \frac{d \log W_D}{d(1/T)} - 1.98 T \frac{PB - E}{PB + E}.$$

It is seen that the correction term can never exceed $1.98 T$.

Curves were prepared from the data of Table III by plotting $\log W_D$ against $1/T$. At the higher pressures these curves were very nearly straight lines. The slopes of these lines, multiplied by 9.14, gives the quantities represented by the first term of the second number of Equation 61. The values thus found are given in the second column of Table XIV.

TABLE XIV.

Pressure.	$-9.14 \times \text{slope.}$	$-1.98T \frac{PB-E}{PB+E}$	q .
10	+79400	+4000	83400
25	80200	+2000	82200
50	81000	0	81000
100	96200	-2000	94200
200	107600	-3600	104000
750	91400	-5200	86200

To calculate the correction term, the relative values of B and E must be known. We shall see that B is equal to $0.23/\sqrt{T_a}$. If we consider that $T_a = T_2$ and thus calculate B for a mean temperature of 3000, we obtain $B = 0.005$. Similarly, we find from (54) $E = 0.26$. With these values

we may calculate the correction term corresponding to the second term of the second member of (61). The results are shown in the third column of Table XIV.

The resulting values for the heat of formation are given in the fourth column. When these are compared with the values obtained at low pressures (given in Table XIII), it is seen that the agreement is reasonably good.

Averaging all the results gives $q = 93000$. It is felt, however, that a properly weighted mean is closer to 90000. We shall therefore adopt for our final value of q .

$$(62) \quad q = 90000 \text{ calories.}$$

This is the heat of formation of 2 grams of hydrogen molecules from atoms at constant pressure and at 3000° K . At constant volume we obtain (at 3000° K .)

$$(63) \quad q_2 = 84000 \text{ calories.}$$

Substituting the above value for q in (50) and integrating, neglecting the small variation of q with the temperature, we find

$$(64) \quad \log K = a - \frac{90000}{4.57T} = a - \frac{19700}{T}.$$

To determine the coefficient a we need to know the value of K at some one temperature. Let us choose 2300° as the temperature at which the low pressure results for K are most nearly free from experimental error. At higher temperatures the term FW_D in the denominator of (43) introduces some uncertainty, whereas at lower temperatures W_D becomes too small compared with W_C (see Tables II and III). By referring to Tables IX, XI, XII, we thus obtain for $T_2 = 2300$:

Pressure.....	0.015	0.039	0.207	1.1	4.4
K.....	0.042	0.085	0.160	0.193	0.163

The mean of these is $K = 0.12$, but since the results at the lowest pressures are more subject to error a more probable value is thought to be

$$K = 0.16 \text{ at } T_2 = 2300.$$

Substituting this in (64), we find

$$a = 7.77.$$

Our final equation for the dissociation constant of hydrogen is

$$(65) \quad \log K = 7.77 - 19700/T.$$

The values of K corresponding to various values of T as calculated from this equation, are given in the second column of Table XV. From these, the corresponding degree of dissociation at atmospheric pressure and at 1 mm. pressure were calculated by solving the equation:

$$(66) \quad x^2/(1-x) = K/P$$

where x is the degree of dissociation and is equal to

$$(67) \quad x = p_1/P.$$

The results of these calculations are given in the third and fourth columns of Table XV.

9. Test of the Theory.

By examining Equations 31 to 34, we see that, by a knowledge of the values of K , q , T_a , B , C , and E , we should be able to calculate W_D for any temperature and pressure. By comparing the results of these calculations with the observations (Table III), we are enabled to test the validity of the assumptions made.

Before making such calculations it is necessary to determine the numerical value of the coefficient B . We have already seen that the maximum value of W_D which we have denoted by W_{\max} , is not subject to error through the uncertainty in the actual pressures within the bulb. Equation 44 is therefore particularly well adapted for the calculation of B .

By substituting the values of W_{\max} from Table VIII in Equation 44, together with the corresponding values of K and E and solving the resulting equations for B , the average result is found to be

$$(68) \quad B = 0.23/\sqrt{T_a}.$$

As a test of the theory from which (44) was derived, we may now employ this value of B to calculate W_{\max} and by Equation 45 to calculate P' , using the values of K from Table XV and the values of E given by (54). For these calculations T_a was taken equal to T_b , since the pressures at which W_D reaches a maximum are so high that this must be approximately true. Moreover, the value of W_{\max} is only dependent on T_b to a very slight degree.

TABLE XVI.

T.	$W_{\max.}$		P'	
	Calculated.	Observed.	Calculated.	Observed.
2000	1.36	1.4	43	25
2200	3.85	4.0	48	50
2400	8.62	8.9	54	50
2600	17.6	16.7	63	50
2800	30.4	30.0	76	50
3000	48.3	48.0	94	50
3200	69.4	75.0	120	100
3400	92.5	117.0	152	100

The calculated values of $W_{\max.}$ and P' thus obtained are placed in Table XVI side by side with the experimentally found figures.

The agreement in the values of $W_{\max.}$ is surprisingly good, especially when it is remembered that the values of K and E , which were used in the calculation, were obtained solely from the experiments at low pressures. The closeness of the agreement over such a wide range of temperature is strong evidence of the correctness of the value of q that was adopted in calculating K .

The discrepancy at the highest temperatures may be explained, I think, as being due to experimental errors caused by electrical leakage through the gas. This effect was noticed strongly at the highest temperatures in the experiment at 4.4 mm. pressure. In this case the discharge through the gas entirely prevented measurements above about 2800°, since the voltage actually decreased as the current was raised. Since the resistance was observed in all cases it was possible to show that this effect was not very serious in the other experiments. It is possible, however, that this effect in an incipient stage may have slightly increased the values of W_D at the highest temperatures, at pressures below 200 mm.

In future experiments this effect could be avoided by using wires of larger diameter so that the potential drop along the wire would be insufficient to ionize the gas.

The agreement between the calculated and observed values of P' in Table XVI is also satisfactory. The calculated gradual increase in P' with increasing temperature is in full accord with the observations.

It must be remembered that the observed pressures were those at which the bulbs were sealed off and that the actual pressures in the bulbs while the filaments were heated must have been much higher. The fact that the calculated values are larger than the observed therefore adds support to the theory.

The value of B obtained above, (68), enables us to calculate the diffusion coefficient D by Equation 32. The shape factor S which is involved in this equation may be calculated from (7), taking $d = 0.00706$ cm. and $b = 3.7$ cm. (see Table V). This gives $S = 1.01$. By substituting this

in (32), together with $q_1 = 42000$ and the value of B from (68), we find
(69) $D_0 = 9.6 \text{ cm}^2. \text{ per sec.}$

This is the value of the diffusion coefficient at 0° C. as obtained by extrapolation downwards from high temperatures by Equation 29. At higher temperatures and at atmospheric pressure, we thus obtain from the same equation, together with (69):

$$(70) \quad D = 2.14 \times 10^{-3} T^{1/2}$$

In the "paper of 1912" D was calculated to be equal to

$$(71) \quad D = \frac{0.514 \times 10^{-3} T^{1/2}}{1 + 77/T}$$

This result was obtained, according to the kinetic theory, on the assumption that the free path of hydrogen atoms and hydrogen molecules are the same. At high temperatures the second term in the denominator of (71) becomes negligible and we thus see that the present results show that the diffusion coefficient of hydrogen atoms through molecular hydrogen is 4.2 times as great as had been previously calculated.

A very thorough test of the theory is afforded by a comparison of the values of W_D calculated according to the theory, with those determined experimentally. In Tables XVII and XVIII the observed and calculated

values have been placed side by side. The "observed" values are taken directly from Table III of Part I. The calculated values were obtained by solving Equation 43 for W_D after substituting it in the numerical values of K , F , T_a and T_2 .

For this purpose the values of K were taken from Table XV, which was obtained directly from Equation 65. At 0.015 and 0.039 mm. pressure T_a was taken to be 300° K., whereas at pressures from 0.207 to 4.4 mm. the values of T_a used in the calculations were those given in Tables IX, XI and XII. At pressures of 10 mm. and more, T_a was taken equal to T_2 . The coefficient F was calculated for each temperature and pressure by substituting the values of B and E from (68) and (54) into Equation 42.

The values of W_D have thus been calculated directly from the dissociation constant, the diffusion coefficient, and the coefficients α_1 and α_2 . An examination of Tables XVII and XVIII shows that the agreement is on the whole excellent; so good, in fact, that it would seem to show not only that we are dealing with a real dissociation of hydrogen into atoms, but that our theory of the mechanism of the process is substantially correct.

10. General Discussion.

The theory which has been used in the present paper was only developed after several attempts had been made to calculate the degree of dissociation by other methods. Each of these other methods, however, seemed to lead to conclusions which could only be reconciled with the experimental data by making many improbable and arbitrary assumptions. These difficulties disappear, however, when we adopt the present theory of the mechanism of the reaction. A brief discussion of the unsuccessful hypotheses will enable us to see that they are untenable.

In attempting to analyze the probable mechanism of the reaction, three possibilities suggest themselves:

1. The dissociation occurs in the heated gas around the wire.
2. The dissociation occurs *on the surface* of the wire by the impact of the molecules and atoms against the surface.
3. The dissociation occurs in the wire or in a surface layer where equilibrium prevails.

The first hypothesis assumes that the tungsten does not act catalytically on the reaction, and is therefore in itself very improbable. Moreover, it leads to conclusions irreconcilable with the experiments at low pressures, where, in a sense, there is no heated gas around the wire.

The second hypothesis seemed at first sight to have much in its favor, and by its aid it was possible to estimate an upper and lower limit to the degree of dissociation.

Whatever the mechanism of the reaction on, or in, the wire, it was possible to analyze the process as follows:

Let ϵ_2 represent, out of all the hydrogen molecules which strike the

wire, that fraction which becomes dissociated into atoms. Similarly, ϵ_1 represents, out of all the atoms that strike the wire, that fraction which recombines to form molecules. We may consider that the reaction actually observed is simply the difference between these opposite reactions. It is clear that neither ϵ_1 nor ϵ_2 can ever exceed unity.

For further progress, it is necessary to make some assumptions regarding these coefficients. It is evident that either ϵ_1 or ϵ_2 or both must vary with the temperature. The simplest assumption is that they are independent of the pressure. By applying Equation 5 we then readily find that the condition for equilibrium is

$$p_1' = \sqrt{2} (\epsilon_2/\epsilon_1) p_2'$$

Since ϵ_1 cannot exceed unity, this gives us a lower limit for the degree of dissociation, provided we can estimate ϵ_2 . By assuming a value for the heat of reaction it is possible to calculate ϵ_2 from W_D by an equation similar to (16). In this way it was concluded that the degree of dissociation at 3200° K. and atmospheric pressure must exceed 5%.¹

In order, however, to account for the manner in which W_D had been observed to vary with temperature and pressure, it was necessary that ϵ_2 should increase with the temperature up to a limiting value of 0.68, but at the same time should decrease in a complicated way as the pressure increased. Similarly, ϵ_1 would have to increase with the pressure and decrease with increasing temperature. This theory gave no clue as to the cause of the variations of ϵ_1 and ϵ_2 .

The fact that ϵ_1 and ϵ_2 were found to be such complicated functions of both temperature and pressure suggested the third hypothesis; namely, that the reaction does not occur at the surface, but that there is an actual equilibrium in the wire which determines the velocity of the reaction. This view was strengthened by the fact that ϵ_1 and ϵ_2 varied with the temperature and pressure in the way that would be expected of the partial pressures of two gases in equilibrium.

On the basis of the third hypothesis, the coefficients ϵ_1 and ϵ_2 lose their fundamental significance, while the coefficients α_1 and α_2 take their place. The fact that the latter coefficients prove to be constant and practically equal to unity over such wide ranges of temperature and pressure is excellent evidence that, in the present theory, we are dealing with the factors that fundamentally determine the velocity of the reaction.

By means of our present theory we are enabled to calculate ϵ_1 and ϵ_2 at any temperature and pressure.

Let us consider the case that hydrogen molecules at pressure p_2 strike the wire, but that the hydrogen atoms formed do not again return to the wire. Then $\epsilon_2 m_2$ represents the rate of formation of atomic hydrogen.

¹ Table XV gives 21 %.

This, however, is equal to the quantity we have called ω (see Equation 17): thus,

$$(72) \quad \omega_2 = \epsilon_2 m_2.$$

Substituting this, together with the value of m_2 (by Equation 5) in (26), we obtain, after placing $\alpha_1 = \sqrt{2} \alpha_2 = 1$

$$(73) \quad K = \sqrt{\frac{T_2}{T_a}} \frac{2p_2 \epsilon_2^2}{1 - \sqrt{2} \epsilon_2}$$

This equation shows clearly that at low temperatures, where K is small, ϵ_2 is inversely proportional to $\sqrt{p_2}$, whereas at higher temperatures it approaches a limiting value of 0.71. Thus the variation of ϵ_2 with the temperature and pressure which it was necessary to assume when working with the second hypothesis, receives a complete explanation by the third hypothesis.

In a similar way, the value of ϵ_1 may be calculated for the case that the wire is surrounded by atomic hydrogen, while the partial pressure of molecular hydrogen is zero. In this case

$$(74) \quad \omega_1 = -\epsilon_1 m_1$$

and we thus find, from (26)

$$(75) \quad K = \sqrt{\frac{T_2}{T_a}} \frac{(1 - \epsilon_1)^2 p_1}{\epsilon_1}.$$

This shows that at low temperatures ϵ_1 must be constant and equal to unity, whereas at high temperatures it decreases and becomes proportional to the pressure. Thus again, the third hypothesis offers a simple explanation of the difficulty encountered in applying the second hypothesis.

It is evident that ϵ_1 and ϵ_2 completely lose their significance when both hydrogen molecules and atoms are present around the wire. We cannot profitably look upon the reaction as being the difference between two opposing reactions taking place *upon the surface*.

In fact, the velocity of the reaction does not follow Gulberg and Waage's Mass Law in the ordinary sense. Neither do diffusion phenomena (at least at low pressures) seem to have any effect on the reaction velocity. The velocity is determined simply by the rate at which the molecules and atoms strike the surface of the wire and the *equilibrium concentrations* of atomic and molecular hydrogen within the wire.

Effect of Bulb Temperature.—In studying chemical reactions at low pressures it has been pointed out¹ that the temperature of the filament and that of the gas molecules striking it can be varied independently of one another. By changing the bulb temperature, the velocity (and internal energy) of the hydrogen molecules striking the filament can be varied over a wide range. If the reaction takes place entirely on the surface in accordance with the second hypothesis, we should expect that the

¹ Langmuir, *THIS JOURNAL*, 35, 105 (1913).

relative velocities of the hydrogen molecules and the tungsten atoms with which they collide, would determine the velocity of the reaction. Because of the small mass of the hydrogen molecules it happens that the average velocity of hydrogen molecules at room temperature or even liquid air temperatures, is much greater than that of tungsten atoms at 3500° . Therefore, the amount of impact between the hydrogen molecules and tungsten atoms depends vastly more on the bulb temperature than it does on the temperature of the filament. In case the impact determines the reaction velocity, we see that the latter should be greatly affected by bulb temperature.

On the other hand, if the reaction takes place in the metal in accord with the third hypothesis, we should not expect the bulb temperature to materially affect the velocity of the reaction. It is to be expected, however, that the bulb temperature might have a slight effect on the coefficient α_2 and thus slightly change the velocity of the reaction.

Some experiments were undertaken to determine whether cooling the bulb in liquid air had any effect on the values of W_D obtained at low pressures (from 0.01 to 0.1 mm.). The results showed conclusively that the bulb temperature was without material effect on the velocity of the reaction. This fact affords additional evidence that the velocity depends primarily on some equilibrium condition within the surface of the wire.

Specific Heat of Hydrogen at High Temperatures.—When hydrogen is heated to a temperature at which appreciable dissociation occurs, the heat absorbed by the reaction may be very large compared with that which would be required if there were no dissociation. We should therefore expect a very large increase in the apparent specific heat of hydrogen at very high temperatures. In Part I we have already briefly discussed Pier and Bjerrum's experiments on the specific heat of hydrogen by the explosion method. We saw that the earlier calculations of the dissociation of hydrogen (paper of 1912) led to apparent specific heats too high to reconcile with the results of the explosion method, unless we assumed that equilibrium was not reached during the short period of the explosion.

In order to compare our present results with the data of the explosion method, we shall calculate the increase in apparent specific heat caused by the dissociation as given in Table XV.

If we heat a gram molecule of hydrogen from 0° K. to T , the number of gram molecules of hydrogen dissociated will be $x/(2-x)$ where x is the degree of dissociation at the temperature T , x being expressed in terms of partial pressures according to (67).

The heat absorbed by this dissociation will be

$$q_2 \, x/(2-x).$$

In comparison with this we may neglect the increase in specific heat

due to the difference in the specific heat of the molecular hydrogen and that of the atomic hydrogen formed (2×2.98).

Pier¹ gives for the *mean* specific heat of hydrogen from room temperature up to $t^\circ \text{C}$.

$$C_v = 4.70 + 0.00045t$$

or in absolute temperatures

$$C_v = 4.578 + 0.00045T$$

The dissociation at higher temperatures would cause an increase in this mean specific heat amounting to

$$\frac{q_2}{T - 273} \cdot \frac{x}{(2 - x)}$$

In Table XIX are given the mean specific heats for a few temperatures, as calculated from Pier's formula, together with those calculated by taking into account the increase due to dissociation. For this calculation the values of x were taken from Table XV and q_2 was taken to be 84000 calories.

3200	6.02	9.40	.56

Siegel, in a recent paper,² discusses in detail the errors of the explosion method. He points out that, owing to a faulty method of calculation, the temperatures given by Bjerrum are considerably too high, in some cases as much as 400° . He then shows that Bjerrum's experiments exhibit certain discrepancies which could be readily explained by assuming a dissociation of the hydrogen. He then says (pages 649-50):

"In order to reconcile Langmuir's results with those of the explosion method, one must assume that in the calculations thus far, the capacity of the system (in the explosion chamber), that is, $\text{CH}_2\text{O} + \text{MCH}_3$, has been taken about 30% too high.

"Such an assumption is impossible. However, if we take for the heat of dissociation of hydrogen, the value 140000 calories instead of the 131000 calories given by Langmuir, we then find by the Nernst approximation formula:

$$\log K = Q/4.57 T + \Sigma \nu \cdot 1.75 \log T + \Sigma \nu C$$

that at 2850° and atmospheric pressure the dissociation is about 11%, which is the value given by Langmuir for 2700° . With this assumption it can be shown that the heat

¹ *Z. Elektrochem.*, 15, 536 (1909).

² *Z. phys. Chem.*, 87, 641 (1914).

capacities of the system. The heat capacity of the system is 12% less than that previously taken. This result is in good agreement with the experimental method. However, I am of the opinion that the heat of dissociation should be at least 150000 calories. On the other hand, it should be emphasized that from my experiments it is not possible to determine with certainty whether or not hydrogen is dissociated at all. And—what is here very significant—by the assumption of such a dissociation, the observed anomalies in the heat losses do not find a sufficient explanation, for the anomalies also occur even at temperatures as low as 2300–2400°, where surely the dissociation of hydrogen can play no part."

Thus, according to Siegel, a dissociation as large as 11% at 2850° can be reconciled with the explosion experiments. If we refer to Table XV we see that we have found the dissociation at 2850° to be 9.2% at atmospheric pressure. This should be ample to account for the anomalies found by Siegel.

Siegel's objection that the dissociation of hydrogen could not account for the discrepancies observed at 2300–2400°, fails to apply to the present results. Siegel does not state his reasons for believing that the heat of dissociation is at least 150000 calories. Such a high value is at complete variance with all the experiments described in the present paper. With the value 84000 calories which we have adopted, the dissociation does not fall off nearly so rapidly at lower temperatures. This is readily seen from the following table:

T.	Siegel. q = 150000.		Langmuir. q = 84000.	
	x.	ΔC/C.	x.	ΔC/C.
2850	0.11	13.0%	0.092	11.0%
2300	0.0049	0.9%	0.014	2.6%

The figures in the second column represent the degree of dissociation calculated from Siegel's data, while those in the fourth column are taken from Table XV. The third and fifth columns give the increase in the "heat capacity of the system" $H_2O + MH_2$ referred to by Siegel. Thus, Siegel calculates that 11% dissociation at 2850° would increase the capacity by 13%. The other figures were obtained from this by proportion, taking into account, however, the effect of the temperature as was done in the preparation of Table XIX.

Thus, on Siegel's assumption of a high heat of dissociation, the effect of the dissociation is to increase the heat capacity at 2850° by 13%, but only by 0.9% at 2300°. It is evidently for this reason that he says that "surely the dissociation can play no part" at such low temperatures as 2300°.

Taking the values for the dissociation as calculated in the present paper, we find that the heat capacity would be increased 11% at 2850 and 2.6% at 2300°, an amount probably sufficient to account for the anomalies found by Siegel.

Thus, the explosion method gives additional evidence for the dissociation of hydrogen and confirms the substantial accuracy of the results.

11. Rate of Formation of Active Hydrogen.

It has been shown¹ that the disappearance of hydrogen in contact with a heated filament is caused by the deposition of atomic hydrogen on the bulb.

The present theory enables us to calculate the rate at which atomic hydrogen should be formed in contact with a tungsten wire. The rate at which atomic hydrogen is deposited on the bulb should naturally be less than that at which it is formed by the wire.

In the paper referred to, it was stated that the disappearance of hydrogen "was often quite marked when the wire was at a temperature as low as 1300° K.," but very few quantitative data at such low temperatures were given. By looking through the original notes of these experiments, I find that at low temperatures the highest rates of disappearance were as follows:

Experiment 160. Filament temperature 1200° K. In seven minutes the pressure fell from 16.4 to 15.6 microns, although at 1100° K. no decrease in pressure could be observed. The surface of the filament was 0.15 sq. cm. The rate of disappearance was 1.4 cubic millimeters of H₂ per minute per sq. cm. of surface.

Experiment 173. With the filament at 1270° the pressure decreased from 16.2 to 15.0 microns in three minutes. The surface of the filament was the same as before. This corresponds to a rate of 3.7 cubic mm. per minute per sq. cm.

In each case the hydrogen continued to disappear at a gradually decreasing rate for a half-hour or more. Because of this fatigue effect we shall here consider only the initial rates.

Let us now calculate the rate at which atomic hydrogen should have been produced by wires at these temperatures. In Equation 26 we may place $p_1 = 0$; $p_2 = P$ and may neglect the second term of the denominator at these low pressures and temperatures. Since the factor $\sqrt{2\pi R}$ is equal to 17.15 and α_1 is unity, we thus obtain

$$(76) \quad K = 325. \sqrt{T_a T_1} \omega^2 / P.$$

In this equation ω is the rate of dissociation of hydrogen in grams per second per sq. cm. of filament surface. Let R be the rate of dissociation of molecular hydrogen in cubic mm. per sq. cm. per minute. We then have

$$(77) \quad R = 7.2 \times 10^8 \omega$$

whence from (76), by placing $T_a = 300$

$$(78) \quad R = 9.6 \times 10^6 \sqrt{KP} T^{-1/2}.$$

¹ THIS JOURNAL, 34, 1310 (1912).

Substituting in this the values of R from Table XX and taking the values of P and T given above, we obtain the values given below as "R cal." For comparison these are placed side by side with those found by experiment.

	T.	R calc.	R obs.
Expt. 160.....	1200	9.8	1.4
Expt. 173.....	1270	27.4	3.7

These results indicate that under the most favorable conditions realized in the experiment, only about one-seventh of the hydrogen dissociated was deposited as "active hydrogen" on the bulb. In the great majority of cases the fatigue effect made the observed rate of clean-up much slower.

The fact that the observed rates are less than the calculated, yet of the same order of magnitude, is a satisfactory confirmation of the theory that the disappearance and activation of hydrogen are caused by its dissociation into atoms.

There is thus quantitative evidence of the dissociation of hydrogen over the whole range of temperature from 1200° to 3500°. The substantial agreement of the calculated and observed results over such a wide range proves that the value we have found for the heat of dissociation, namely, 84000 calories, cannot be far from correct.¹

12. Experiments with Mixtures of Hydrogen and Nitrogen.

Some experiments have been made to determine the heat losses from tungsten wires in mixtures of nitrogen and hydrogen. The wire was the same as that previously used in the experiments with hydrogen. The bulbs, after being exhausted in the usual way, were filled with the mixture of gases, the total pressure in each case being 600 mm. Mixtures containing 1.25, 3.0, 10.0 and 30% of hydrogen were used. The results given in Table XX were obtained by subtracting from the observed watts per centimeter, the energy radiated (W_R). These figures are directly comparable with those given in Table I of Part I.

TABLE XX.

Diam. of wire 0.00706 cm.		Watts per cm. carried by mixture.				Total pressure 600 mm.	
T.	W_R .					W_C in N ₂ .	W_C in H ₂ .
		$p_o = 7.5$ mm.	$p_o = 18$ mm.	$p_o = 60$ mm.	$p_o = 180$ mm.	$S = 1.36$.	$S = 1.18$.

3000	1.37	1.10	2.20	1.92	4.18	3.96

To obtain the heat carried from the wire by the dissociation, it is necessary to subtract W_C . In the last two columns of Table XX are the calculated values of W_C for pure nitrogen and hydrogen at pressures of 600 mm. These are obtained by multiplying S by the values of $\varphi_2 - \varphi_1$ given in Tables III and IV. For the mixture of hydrogen and nitrogen W_C was found by interpolating linearly between the values calculated for the pure gases. By subtracting these results from the watts per cm. of Table XX the values of W_D given in Table XXI as "cal." were obtained. The smallness of the differences at lower temperatures shows that the heat carried by convection in mixtures of gases is approximately an additive function of the partial pressures (the total pressure remaining constant).

To calculate the values of W_D for mixtures of gases according to our theory we need to start from Equation 27. From this we can eliminate p_1 and p_2 as before, by means of Equation 30. The significance of P and p_2 , however, is now somewhat different, so we must proceed from this point in a slightly different way. In Equation 30, P is the total pressure, and p_1 the partial pressure of atomic hydrogen. We then have

$$(79) \quad p_2 = p_0 - \frac{1}{2}p_1$$

where p_0 is the partial pressure of molecular hydrogen before dissociation occurs and p_2 is the partial pressure of molecular hydrogen after dissociation.

In the present case we may place $T_0 = T_2$; $P = 600$, $S = 1.34$, and $q_1 = 42000$. From (30) we thus find

$$(80) \quad p_1 = 946W_D / (D_0 \sqrt{T}).$$

Combining (79) and (80) with (27), we find

$$(81) \quad K = \frac{W_D^2 (946/D_0 \sqrt{T} + E)^2}{p_0 - W_D (473/D_0 \sqrt{T} + E)}$$

where E is given by (34).

By trial it was found that (81) gives the best agreement between the observed and calculated values of W_D if D_0 is placed equal to 2.5.

Calculating E by (54) it is evident that E is negligible compared to

$473/2.5\sqrt{T}$ over the whole range of temperatures covered by the experiments. Equation 81 thus simplifies to

$$(82) \quad W_D = \sqrt{\frac{K p_0 T}{144000}} \times \sqrt{1 - \frac{190}{p_0 \sqrt{T}}} W_D.$$

This quadratic equation can be conveniently solved for W_D by using a series of approximations, since the second radical is always close to unity. In this way, by taking K from Table XV, the values of W_D for different temperatures and partial pressures have been calculated. The results are placed side by side with the observed values in Table XXI.

The agreement is entirely satisfactory, considering the crudeness of some of the assumptions made.

The theory receives additional confirmation through the fact that the observed values of W_D increase in proportion to the square root of the partial pressure as demanded by the theory, whereas at lower temperatures the observed values of W_C increase linearly with the partial pressure.

From the value of D_0 we may conclude by (29) that the diffusion coefficient of hydrogen atoms through nitrogen at high temperatures and atmospheric pressure is

$$(83) \quad D = 2.5 (T_a/273)^{1/2}.$$

Comparing this with (69) we see that the ratio of the diffusion coefficient of hydrogen atoms through hydrogen to that through nitrogen is $9.6/2.5 = 3.84$.

If we calculate the free path of hydrogen atoms through nitrogen according to the principles of the kinetic theory, using Equations 20 and 21 on page 865 of the "paper of 1912," we obtain

$$(84) \quad D_{\text{cal.}} = 2.16 (T/273)^{1/2}.$$

This agrees well with the diffusion coefficient calculated from the experiments (Equation 83). We have previously remarked that the observed rate of diffusion of hydrogen atoms through molecular hydrogen was found to be 4.2 times greater than that calculated. Evidently hydrogen atoms behave abnormally when diffusing through molecular hydrogen, but not when diffusing through nitrogen. This is probably caused by the hydrogen atoms going, we might say, through the hydrogen molecules by combining with one atom in a molecule with which it collides and thus liberating the other. This effect is probably entirely analogous to the abnormal mobility of the H and OH ions in aqueous solutions.

13. Summary.

1. Previous calculations of the degree of dissociation of hydrogen, from experiments on the heat losses from tungsten wires in hydrogen, conflicted rather seriously with Bjerrum's determinations of the specific heat of hydrogen by the explosion method. The weak point in the method

of calculation was a rather arbitrary assumption regarding the diffusion coefficient of atomic hydrogen through ordinary hydrogen.

2. This apparent discrepancy suggested that the actual amount of dissociation might be somewhat less than that previously calculated, but did not indicate that the abnormal heat conductivity of hydrogen at high temperatures was not due to dissociation.

3. The qualitative evidence of such a dissociation seems conclusive. Thus, not only does hydrogen show an entirely abnormal increase in heat conductivity, but this heat conductivity actually increases as the pressure is lowered.

A large amount of chemical evidence has also been accumulated. If hydrogen at low pressures comes into contact with metallic wires at temperatures above 1300° K., part of the hydrogen is converted into an active modification which remains adsorbed on glass surfaces for long periods of time. This active hydrogen can react at room temperature with oxygen or with many reducible substances, or can dissolve in metals such as platinum. There are good reasons for thinking that this active hydrogen is hydrogen in the atomic condition.

4. A series of experiments were made to measure, more accurately than hitherto, the heat losses from a tungsten wire at temperatures from 800° to 3500° K. and at pressures of hydrogen ranging from 0.01 mm. up to atmospheric pressure. Similar experiments were made with nitrogen.

5. At temperatures below that at which dissociation occurs the heat loss from the wires decreases steadily as the pressure is lowered. Only at pressures above 200 mm. do convection currents play any important part. Below this pressure the decrease in the heat loss is due to the temperature discontinuity, first observed by Smoluchowski. The theory of this effect is developed for the case of small wires at very high temperatures and the results are found to be in good agreement with the experiments.

6. The normal heat conductivity is separated from the abnormal effect due to dissociation, and a table is prepared (Table III) giving the heat carried from the wire by the dissociation, at various temperatures and pressures. With nitrogen there is no abnormal increase in heat loss at high temperatures.

7. The following theory of the phenomena occurring in and around the wire is proposed:

The dissociation of the hydrogen does not occur in the space around the wire, nor by the impact of molecules against its surface, but takes place only among the hydrogen molecules which have been absorbed (dissolved?) by the metal of the wire. Within the metal the reaction occurs so rapidly that equilibrium may be assumed to prevail at all times.

The equilibrium constant within the metal may, however, be very different from that in the gas phase.

It is assumed that there is no "adsorption film" on the surface of the wire through which the hydrogen has to diffuse, but that the absorption takes place by the collision of the molecules (or atoms) against the surface of the wire. A certain proportion of the molecules striking the surface may be reflected without absorption. Thus, of all the hydrogen molecules striking against the surface, we assume that a certain fraction α_2 is absorbed, while the fraction $1 - \alpha_2$ is reflected. Similarly, of all the hydrogen atoms striking the surface, the fraction α_1 is absorbed.

In general, the partial pressures of atomic hydrogen in the gas immediately surrounding the wire will not be that corresponding to the equilibrium at the temperature of the wire. The difference between these two partial pressures may be looked upon as a "drop in concentration" at the surface of the wire strictly analogous to Smoluchowski's "temperature drop" in the case of heat conduction and to Kundt and Warburg's "slip" in the case of experiments on the viscosity of gases.

The partial pressure of atomic hydrogen immediately around the wire depends on: 1st, the rate at which atomic hydrogen escapes from the wire; 2nd, the rate at which atomic hydrogen is absorbed by the wire; and 3rd, the rate at which it can diffuse away from the wire.

8. From the viewpoint of this theory it has been possible, by thermodynamical reasoning, to develop a quantitative theory by which the dissociation constant K (in the gas phase) may be calculated in terms of W_D the heat carried from the filament by dissociation; q_1 the heat of reaction; D the diffusion coefficient, and the two coefficients α_1 and α_2 .

The resulting general Equation 31 is of the form (neglecting constant factors)

$$K = \frac{(W/q)^2 (P/D + 1/\alpha_1)^2}{P - (W/q) (P/D + 1/\alpha_2)}$$

where P is the total pressure.

9. By comparing this equation with the experimental data, it is found possible to so choose the quantities K , q , D , α_1 and α_2 that the resulting equation agrees excellently with the experiments at all temperatures and pressures. At the same time, the values of K conform to the thermodynamical requirement given by van't Hoff's equation

$$d \ln K/dT = q/RT^2.$$

The agreement between the theory and the experiments is shown in Tables XVII and XVIII, where the observed and calculated values of W are placed side by side.

10. The values of the quantities K , q , D , α_1 and α_2 which were used in these calculations, and which were found to give the best agreement between experiment and theory, are as follows:

Dissociation Constant K.—Let us define the dissociation constant K by the equation:

$$(22) \quad K = p_1^2/p_2$$

p_1 and p_2 being the partial pressures (in mm.) of atomic and molecular hydrogen, respectively. Then it is found that

$$(65) \quad \log_{10} K = 7.77 - 19700/T.$$

Values of K calculated from this equation for temperatures from 1200 to 4000° have been given in Table XV, together with the corresponding degrees of dissociation at pressures of 760 mm. and 1 mm. The following is a comparison of these results with those obtained previously (in the year 1912):

DEGREE OF DISSOCIATION AT 760 MM.

Temp. ° K.....	2000	2300	2500	3100	3500
Results in 1912.....	0.0013	0.012	0.039	0.44	0.84
Results in 1915.....	0.0033	0.014	0.031	0.17	0.34

In the range from 2200–2600°, the results are nearly identical, but at higher and lower temperatures the differences become large.

Heat of Formation of Hydrogen Molecules.—By applying van't Hoff's equation to the foregoing data, we find the heat of reaction for two grams of hydrogen to be

84000 calories at constant volume
90000 calories at constant pressure

In 1912 the value given was 130000 calories at constant volume.

Diffusion Coefficient of Atomic Hydrogen in Molecular Hydrogen.—This quantity is found to be

$$(70) \quad D = 2.14 \cdot 10^{-3} T^{3/2}.$$

This result is 4.2 times greater than that found previously by calculation from the principles of the kinetic theory. This difference suggests that the hydrogen molecules are more or less "transparent" to hydrogen atoms. The effect is probably quite analogous to that of the abnormal mobility of the H and OH ions in aqueous solutions.

The Coefficients α_1 and α_2 .—The coefficient α_1 is found to be constant and equal to unity, while α_2 is apparently constant and equal to 0.68. In other words, *all the hydrogen atoms striking the filament are absorbed by it and 68% of all the hydrogen molecules are absorbed.* The velocity of the reaction is thus determined practically entirely by the equilibrium conditions within the wire. The fact that these coefficients are found to be so nearly equal to unity is excellent evidence that in the present theory we are actually dealing with the fundamental factors determining the velocity of the reaction.

11. Other possible theories of the mechanism of the reaction are discussed, but no other is found which agrees at all well with the facts.

12. The apparent increase in specific heat caused by the dissociation is calculated. Even at temperatures as low as 2000° the effect should be perceptible. The magnitude of the effects found is, according to statements of Seigel, of the right order to account fully for certain anomalies in the experiments of Bjerrum. Therefore, the results of the explosion method, instead of conflicting with the present determinations of the degree of dissociation, may be regarded as additional evidence in their favor.

13. The rate at which hydrogen at very low pressures is dissociated by a tungsten wire at $1200-1500^{\circ}$ has been calculated according to the theory and is found to be 8-10 times greater than the *greatest* observed rate at which active hydrogen was deposited on glass surfaces. In view of the marked fatigue effects characteristic of this adsorption of active hydrogen by glass, the agreement is close enough to lend further support to the theory. The quantitative evidence of the dissociation of hydrogen may therefore be said to extend over a temperature range from 1200 to 3500° K., in which the degree of dissociation increases in the ratio 1:170000.

14. Experiments on the heat losses from tungsten wires in mixtures of nitrogen and hydrogen yield results also in accord with the theory. See Table XXI. The diffusion coefficient of hydrogen atoms through nitrogen is found to be

$$D = 2.5 (T/273)^{3/2}$$

which is in excellent agreement with a value calculated by the kinetic theory.

SCHNECTADY, N. Y.

THE FREE ENERGY OF SOME CARBON COMPOUNDS.

By GILBERT N. LEWIS AND MERLE RANDALL.

Received December 15, 1914.

Elementary Forms of Carbon.

Of the numerous known forms of carbon only two, graphite and diamond, appear to be true chemical individuals. Indeed it is possible that substances like coal, charcoal, and coke should be regarded, not as elementary carbon, but as mixtures of hydrocarbons of low hydrogen content. Passing from benzene through naphthalene to more unsaturated compounds of higher molecular weight there seems to be no limit to the ratio between the number of carbon atoms to the number of hydrogen atoms in a hydrocarbon molecule. However, there are certain of the so-called amorphous forms of carbon, such as the one produced by the decomposition of pure carbon monoxide, which must be regarded as pure, but of which the properties vary according to the method of preparation. They

may consist of very minute crystals of varying size, but it is more probable that they should be regarded as liquids of enormous viscosity, or even sponge-like gels, of which the density, heat capacity and other characteristic properties are determined by the conditions under which they are formed.

In determining the difference in free energy of the elementary forms of carbon, it is impossible to proceed as we have in the case of sulfur, since no transition points are known. Schenck and Heller¹ believed that they had discovered, in the equilibrium between carbon, iron, ferrous oxide, and the oxides of carbon, different equilibrium pressure curves for the different modifications of carbon, the pressure being higher with amorphous carbon and diamond than with graphite. Theoretically it is barely conceivable that, by the intervention of a phenomenon analogous to supercooling, true equilibria involving in one case diamond and in another case graphite might be obtained. But it has been shown by Falcke² that under the conditions of Schenck and Heller's experiments this certainly is not the case. Pring and Fairlie³ in their investigation of the equilibrium between carbon, hydrogen, and methane obtained in all cases a larger proportion of methane with amorphous carbon than with graphite, but on standing, with amorphous carbon, the percentage of methane diminished as the carbon became graphitized, until the conditions obtained with pure graphite were established. It is possible that in the early stages of their experiments with amorphous carbon there was a close approach to equilibrium between this substance and the gaseous mixture. Aside from these investigations we have no chemical data which enable us to calculate the difference in free energy of the forms of carbon.

In order, therefore, to determine the difference in free energy between the two modifications of definite properties, graphite and diamond, we shall make use of a method which we have not hitherto employed in these calculations. Numerous attempts have been made to calculate free energy changes from thermal data alone, notably by Nernst and his collaborators. For the most part these calculations have involved assumptions of only approximate validity, such as Trouton's rule or the Nernst theorem concerning the so-called chemical constants. But one generalization has been developed which appears to possess universal validity. It was first clearly stated by Planck, and may be called the Second Law of Entropy. We may express this law as follows: *Every substance⁴ possesses zero entropy at the absolute zero of temperature.*

¹ Schenck and Heller, *Ber.*, 38, 2139 (1905).

² Falcke, *Ber.*, 46, 743 (1913).

³ Pring and Fairlie, *J. Chem. Soc.*, 101, 91 (1912).

⁴ This law is true of every actual substance. The entropy of an ideal gas, that is, of a gas at zero pressure, is indeterminate at the absolute zero.

Let us consider one mol. of a substance, of which the heat capacity at constant pressure is C_p . Now if it be cooled at constant pressure from the temperature T to the absolute zero, the total diminution in entropy is

$S_T - S_0 = \int_0^T \frac{C_p}{T} dT$. According to the law just stated $S_0 = 0$. Hence

$$S_T = \int_0^T \frac{C_p}{T} dT = \int C_p d \ln T. \quad (1)$$

Now in any chemical reaction $aA + bB + \dots = cC + dD + \dots$, if S_A is the molal entropy of A, etc.,

$$\Delta S = cS_C + dS_D + \dots - aS_A - bS_B - \dots$$

If the heat capacity of each substance, at the pressure at which it occurs in the reaction, is known as a function of the temperature, down to the absolute zero, we may calculate the entropy of each substance at the temperature in question and thus obtain ΔS for the reaction. But we also have the thermodynamic relation,

$$T\Delta S = \Delta H - \Delta F; \quad (2)$$

hence if the heat of reaction and the heat capacity curves of the several substances are accurately known we may determine exactly the value of ΔF .

The calculation of the entropy from the heat capacity curves can be carried out with a high degree of accuracy in many cases, owing to the fact that, since the heat capacity falls so rapidly with diminishing temperature, the range of very low temperatures, where accurate measurements are most difficult, contributes almost nothing to the entropy. According to the theory of Debye¹ the heat capacity of crystalline substances belonging to the regular system is proportional to the cube of the temperature, and Lewis and Adams² have shown that it is probable that this is true of all substances at very low temperatures. In the range of validity of this law it follows from (1) that

$$S = 1/3 C_p. \quad (3)$$

At higher temperatures we might obtain the integral of Equation 1 by the use of one of the various heat capacity equations that have been proposed. But a far simpler method, which is perfectly general and involves no assumptions, consists in plotting C_p as ordinate and $\ln T$ as abscissa and determining the area under the curve up to the temperature in question. We shall illustrate this method in determining the difference in free energy between graphite and diamond.

$C_G = C_D$.—Since graphite is not only the stable form, but is also the

¹ Debye, *Ann. Physik.*, 39, 789 (1912).

² Lewis and Adams, *Physic. Rev.*, [2] 4, 331 (1914).

one which has been used in high temperature equilibrium measurements, we shall consider it the standard state of elementary carbon. The most reliable measurements of the heat capacity of diamond and of graphite seem to be those of Weber¹ at high temperatures, and of Nernst² and Koerpf³ at low temperatures. We have attempted in Fig. 1 to give the most probable curves

Fig. 1.—Heat Capacity of Diamond and Graphite.

on the basis of existing data for the heat capacities of the two substances.⁴ The ordinates are the values of C_p , the molal heat capacity, in calories per degree, and the abscissas are the common logarithms of T . It is evident that the area under the diamond curve below the temperature

¹ Weber, *Phil. Mag.*, [4] 49, 161, 276 (1875); *Ann. Physik. Chem.*, [2] 154, 367 (1875).

² Nernst, *Ann. Physik.*, [4] 36, 395 (1911).

³ Koref, *Ibid.*, [4] 36, 49 (1911).

⁴ At the highest temperatures the results of Weber were obtained by comparing diamond and graphite with platinum dropped from the same temperature into a double calorimeter. His furnace temperatures were estimated from the best data then existing for the specific heat of platinum. Those values now appear to be erroneous and we have, therefore, recalculated Weber's results at the three high temperatures where this method was employed, using White's formula for the specific heat of platinum, *Am. J. Sci.*, [4] 28, 334 (1909). We thus find for C_p (graphite) 4.85 at 950° A, 4.88 at 1150°, 4.95 at 1320°; and C_p (diamond) 4.80 at 913° A, 4.88 at 1124°, 4.82 at 1331°. It is to be noted, however, that Weber's results at lower temperatures as well as the theoretical curve obtained for diamond as a substance in the regular crystalline system, point to values nearer to those originally given by Weber, and it is possible that through some compensating error his results as originally given are more accurate than our recalculated values.

corresponding to $\log T = 1.4$ is entirely negligible. At this low temperature the graphite has not yet reached the point where it obeys the T^3 law, but we estimate that the entropy at this temperature is about 0.03, an almost negligible amount. By counting squares up to $T = 298.1$, $\log T = 2.474$, we find for the area under the graphite curve 47.80 of the squares shown in the figure. Owing to the scale of the plot, and to the fact that we are using common logarithms, we must multiply this figure by $2.303/80$ and thus obtain 1.37; adding 0.03 we find for graphite $S_{298} = 1.40$. Similarly we find for diamond $S_{298} = 0.60$. Hence we find for our reaction

$$\Delta S_{298} = -0.80 \text{ cal. per degree.} \quad (4)$$

The older determinations of the heats of combustion of graphite and diamond were too inaccurate to give ΔH , but the recent very careful work of Roth and Wallasch¹ indicates that the heat of combustion of diamond is larger than that of graphite by 280 cal. Thus $\Delta H_{298} = 280$. In general $\Delta F = \Delta H - T\Delta S$, hence

$$C_G = C_D; \Delta F^\circ_{298} = 280 + 298 \times 0.80 = 520. \quad (5)$$

Another form of our fundamental free energy equation is

$$d(\Delta F)/dT = -\Delta S.$$

If the statement of Weber is correct that at higher temperatures the heat capacity of diamond approaches but never exceeds that of graphite, then ΔS is always negative, and ΔF remains positive at all temperatures, increasing with increasing temperatures. At all temperatures, therefore, graphite is more stable than diamond at atmospheric pressure. In the formation of diamond, then, we may have another illustration of the frequent phenomenon that an unstable modification appears before the stable one has an opportunity to form. But if diamond is formed at very high pressures it may be the stable form, and if the value given above for ΔF°_{298} is correct we may calculate the transition pressure. Taking the volume per gram atom of diamond as 3.4 cc., and of graphite as 5.5 cc., the increase in free energy of either substance in compression from 1 atmos. to p atmos. is (neglecting the compressibility) $\Delta F = v(p-1)$.² Substituting the atomic volumes and converting from cubic centimeter-atmospheres to calories, and using the above value of ΔF°_{298} we find that at room temperature diamond will be more stable than graphite at pressures above 10,000 atmos. At higher pressures, assuming any reasonable values for the coefficient of expansion, the transition pressure will increase rather than diminish.

Oxides of Carbon.

$C + CO_2 = 2CO$.—The equilibrium between carbon, carbon monoxide and carbon dioxide has been studied by several investigators. The work

¹ Roth and Wallasch, *Ber.*, 46, 896 (1913).

² Lewis, "Free Energy of Chemical Substances," Equation 11, *THIS JOURNAL*, 35, 16 (1913).

of Boudouard¹ gave the order of magnitude of the equilibrium constant and its change with the temperature, but his work has been superseded by the very careful measurements of Rhead and Wheeler.² In their experiments, wood charcoal was used, which was treated with chlorine at 1000° for 24 hrs., and later with other gases for several days at the same temperature, so that we may assume that their carbon was, at least on the surface, in the form of graphite. The heat capacity of an element at temperatures below the range of validity of the law of Dulong and Petit cannot be represented by a simple algebraic expression. We find, however, that the heat capacity curve of graphite, between 0° C. and 2000° C. may be fitted with sufficient accuracy for our purpose by the quadratic equation,

$$C_G; C_p = 1.1 + 0.0048T - 0.0000012T^2. \quad (6)$$

From our previous paper,³

$$\text{CO}_2; C_p = 7.0 + 0.0071T - 0.00000186T^2.$$

$$\text{CO}; C_p = 6.5 + 0.0010T.$$

Hence

$$\Delta F = 4.9 - 0.0099T + 0.00000306T^2.$$

$$\Delta H = \Delta H_0 + 4.9T - 0.00495T^2 + 0.00000102T^3.$$

$$\Delta F^\circ = \Delta H_0 - 4.9T \ln T + 0.00495T^2 - 0.00000051T^3 + IT.$$

The value of ΔH_{291} can be obtained from the heat of formation of CO_2 from graphite which is given by Roth and Wallasch⁴ as 94250, and from the heat of combustion of CO for which Berthelot gives 68300 and Thomsen 67960, the mean being 68100. Combining these two values $\Delta H_{291} = 41950$, and from the above equation $\Delta H_0 = 40910$.

The values of I at the various temperatures of Rhead and Wheeler's measurements can now be obtained, and are given in Table I, in which

TABLE I.

T.	% CO.	% CO ₂ .	K.	ΔF° .	I.

¹ Boudouard, *Compt. rend.*, 130, 132 (1900).

² Rhead and Wheeler, *J. Chem. Soc.*, 97, 2178 (1910). In the recent work of Clement, U. S. Bureau of Mines, *Bull.* 17 (1911), the rate of this reaction was chiefly studied. His estimate of the equilibrium constant is evidently erroneous, owing to the fact that his experiments were of too short duration to permit the attainment of equilibrium conditions.

³ Lewis and Randall, *THIS JOURNAL*, 34, 1128 (1912).

⁴ Roth and Wallasch, *loc. cit.*

the first column gives the absolute temperatures, the next two the percentages of CO and of CO₂ in the equilibrium mixture at atmospheric pressure, the fourth the equilibrium constant, the fifth $\Delta F^\circ = -R'T \ln K$, and the sixth the values of I obtained from the several values of ΔF° .

The values of I show excellent constancy, and considering the difficulties of the experiment, this must be regarded as one of the most satisfactory investigations of high temperature equilibrium. Using the mean value of I we have

$$C_G + CO_2 = 2CO; \Delta F^\circ_{298} = 29240$$

$$\Delta F^\circ = 40910 - 4.9T \ln T + 0.00495T^2 - 0.00000051T^3 - 12.66T. \quad (7)$$

$CO_2 + H_2 = CO + H_2O(g)$. This reaction, known as the water gas reaction, has been the subject of numerous investigations. The formulas for the heat capacities of these four gases are given in our previous paper¹ from which we find

$$\Delta F = 1.81 - 0.0089T + 0.00000408T^2.$$

For the formation of water vapor from its elements, $\Delta H_o = -57410$,² and for the formation of carbon dioxide from carbon monoxide and oxygen, $\Delta H_o = -67510$ as we show in the next reaction. Hence for the water gas reaction $\Delta H_o = 10100$ and

$$\Delta F^\circ = 10100 - 1.81T \ln T + 0.00445T^2 - 0.00000068T^3 - 0.54T. \quad (8)$$

The value of I = -0.54 is obtained from the important determinations of the equilibrium in this reaction by Hahn³ and by Haber and Richardt.⁴ Their results are summarized in Tables II and III. The first row gives the absolute temperature of the measurements, the second the equilibrium constant, and the third the value of I calculated therefrom.

In Hahn's work the gases were allowed to stream by a catalyzer and were rapidly cooled, but, as pointed out by Haber⁵ in his critical résumé of this equilibrium, the discrepancy between Hahn's measurements at high and low temperatures is due to the difficulty in cooling the mixture from a high temperature rapidly enough to prevent the continuance of the re-

¹ Lewis and Randall, *THIS JOURNAL*, **34**, 1128 (1912).

⁵ Haber, "Thermodynamics of Technical Gas Reactions."

action. This criticism apparently does not hold for Hahn's lower temperatures and we may take from his first three measurements $I = -0.56$. The measurements of Haber and Richardt were obtained by a study of the temperature and composition of the gases in the free flame. The agreement of the values of I with one another, and with those of Hahn at low temperature, not only give us great confidence in the reliability of the experimental results, but also in the equations which we have chosen to express the heat capacities of the several gases involved. The discussion given in Haber's book shows how extremely difficult it is to interpret high temperature equilibrium measurements when there is any serious doubt concerning the true heat capacity values. We have chosen as a final mean $I = -0.54$, hence

$\text{CO} + \frac{1}{2}\text{O}_2 = \text{CO}_2$.—Another important check upon the calculation just made is furnished by the study of the dissociation of carbon dioxide, for by combining (8) with Equation 56 of our paper on oxygen and hydrogen compounds,

We may now proceed to calculate the free energy of this reaction from direct measurements of the dissociation of carbon dioxide. The heat capacity values we shall take once more from our paper on specific heats and find $\Delta I' = -2.75 + 0.0056T - 0.00000186T^2$. We have already found $\Delta H_{291} = -68100$, whence $\Delta H_0 = -67510$ and

$$\Delta I^\circ = -67510 + 2.75T \ln T - 0.0028T^2 + 0.00000031T^3 + IT.$$

The calculation of I from the experiments of Nernst and von Wartenberg,¹ Langmuir² and Löwenstein³ is shown in Table IV. The first column gives the absolute temperature of the measurements, the second

the percentage dissociation of carbon dioxide at atmospheric pressure, the third the equilibrium constant $p_{\text{CO}_2}/(p_{\text{CO}}p_{\text{O}_2}^{1/2})$, the fourth the value of I , and the fifth the author.

The mean of the several values of I is 4.43, or 4.69 if we exclude the uncertain value of Löwenstein and the one exceptionally low value of Langmuir. On the other hand by direct subtraction of Equation 8 for the water gas reaction from Equation 56 of our previous paper for the free energy of formation of water vapor we find $I = 4.26$. The agreement is very satisfactory. We shall give greater weight to the water gas reaction which was studied at lower temperatures and choose $I = 4.30$ as the final value, whence

$$\Delta F^\circ = -67510 + 2.75T \ln T - 0.0028T^2 + 0.00000031T^3 + 4.30T. \quad (10)$$

$\text{C}_\text{G} + \frac{1}{2}\text{O}_2 = \text{CO}$.—Adding Equations 7 and 10 gives

$$\Delta F^\circ = -26600 - 2.15T \ln T + 0.00215T^2 - 0.0000002T^3 - 8.36T. \quad (11)$$

$$\Delta F^\circ_{298} = -32560.$$

$\text{C}_\text{G} + \text{O}_2 = \text{CO}_2$.—Adding Equations 10 and 11,

$$\Delta F^\circ = -94110 + 0.60T \ln T - 0.00065T^2 + 0.00000011T^3 - 4.06T. \quad (12)$$

$$\Delta F^\circ_{298} = -94360.$$

Carbonic Acid and Its Ions.

$\text{CO}_2 + \text{H}_2\text{O}(\text{l}) = \text{H}_2\text{CO}_3(\text{aq})$.¹—The solubility of CO_2 in water at 25° at a partial pressure of 1 atm. is 0.0338 mols per liter according to the entirely concordant measurements of Bohr and Bock² and of Just.³ Hence

$$\Delta F^\circ_{298} = -R'T \ln 0.0338 = 2010. \quad (13)$$

$\text{H}_2 + \text{C}_\text{G} + \frac{3}{2}\text{O}_2 = \text{H}_2\text{CO}_3(\text{aq})$.—Adding Equations 12, 13, and Equation 54 of our previous paper,

$$\begin{array}{ll} \text{C}_\text{G} + \text{O}_2 = \text{CO}_2 & ; \quad \Delta F^\circ_{298} = -94360 \\ \text{CO}_2 + \text{H}_2\text{O} = \text{H}_2\text{CO}_3(\text{aq.}) & ; \quad \Delta F^\circ_{298} = 2010 \\ \text{H}_2 + \frac{1}{2}\text{O}_2 = \text{H}_2\text{O}(\text{l}) & ; \quad \Delta F^\circ_{298} = -56620 \end{array}$$

$$\text{H}_2 + \text{C}_\text{G} + \frac{3}{2}\text{O}_2 = \text{H}_2\text{CO}_3(\text{aq.}); \quad \Delta F^\circ_{298} = -148970 \quad (14)$$

$\text{H}_2\text{CO}_3(\text{aq.}) = \text{H}^+ + \text{HCO}_3^-$.—Walker and Cormack⁴ found for the first dissociation constant of carbonic acid $K_{291} = 3.04 \times 10^{-7}$. The heat of this reaction is the heat of mixture of 1 mol H_2CO_3 and 1 mol NaOH , less the heat of neutralization of 1 equivalent of a strong acid. From

¹ Of course we make no assumption that the carbon dioxide dissolved in water is all in the form of H_2CO_3 . For the purpose of the thermodynamic calculations in which we are engaged it is immaterial whether the substance is all H_2CO_3 , or in part CO_2 or higher hydrates than H_2CO_3 .

² Bohr and Bock, *Ann. Physik*, [3] 44, 318 (1891).

³ Just, *Z. physik. Chem.*, 37, 342 (1901).

⁴ Walker and Cormack, *J. Chem. Soc.*, 77, 5 (1900).

Thomsen's measurements $\Delta H = 2700$, and, applying the van't Hoff formula, $K_{298} = 3.39 \times 10^{-7}$. Hence

$$\Delta F_{298}^{\circ} = 8830. \quad (15)$$

$\frac{1}{2}\text{H}_2 + \text{C}_G + \frac{3}{2}\text{O}_2 + \ominus = \text{HCO}_3^-$.—Combining Equations 14, 15, and Equation 9 of our previous paper,

$$\frac{1}{2}\text{H}_2 + \text{C}_G + \frac{3}{2}\text{O}_2 + \ominus = \text{HCO}_3^-; \quad \Delta F_{298}^{\circ} = -140140 \quad (16)$$

$\text{HCO}_3^- = \text{H}^+ + \text{CO}_3^{--}$.—The second dissociation constant of carbonic acid has been the subject of investigations by Bodländer,¹ McCoy,² and Auerbach and Pick.³ The uncertainty in this constant seems to be due not so much to the experiments as to the difficulty of interpreting them. We know very little about the concentration of the ion NaCO_3^- or about the concentration and activity of CO_3^{--} in mixtures of sodium carbonate

and acid carbonate. McCoy determined the ratio $\frac{(\Sigma \text{NaHCO}_3)^2}{(\Sigma \text{H}_2\text{CO}_3)(\Sigma \text{Na}_2\text{CO}_3)}$ in solutions M , $0.3M$, and $0.1M$ with respect to NaHCO_3 , and found 3120, 4460, and 5290, respectively. By a rough extrapolation from these figures we find 6300 at high dilution, where the two salts may be regarded as completely dissociated, and the quotient becomes $\frac{(\text{HCO}_3^-)^2}{(\text{H}_2\text{CO}_3)(\text{CO}_3^{--})}$.

Dividing by this quotient the first dissociation constant of carbonic acid given above we find $K_{298} = (\text{H}^+)(\text{CO}_3^{--})/(\text{HCO}_3^-) = 5.4 \times 10^{-11}$ as the second dissociation constant of carbonic acid, whence

$$\Delta F_{298}^{\circ} = 14010. \quad (17)$$

$\text{C}_G + \frac{3}{2}\text{O}_2 + 2\ominus = \text{CO}_3^{--}$.—Using once more the fact that the free energy of hydrogen ion is taken as zero, and combining Equations 16 and 17,

$$\Delta F_{298}^{\circ} = -126130. \quad (18)$$

Methane.

$\text{C}_G + 2\text{H}_2 = \text{CH}_4$.—Of all the hydrocarbons the only one for which we have data reliable enough to warrant the present calculation of the free energy is methane.

The specific heat of methane has been determined only through a small range of temperatures. Regnault found $C_p = 9.5$ at about 108° . As might be expected, this is a somewhat higher value than that given by the

¹ Bodländer, *Z. physik. Chem.*, **35**, 23 (1900).

² McCoy, *Am. Chem. J.*, **29**, 437 (1903).

³ Auerbach and Pick, *Arb. Kais. Gesundh.*, **38**, 243 (1911).

equation for ammonia. We will modify it and write

$$\text{CH}_4: C_p = 7.5 + \quad (19)$$

Combining this with the equation already given for hydrogen and graphite,

$$\Delta F = -16300 + 6.6T + 0.0016T^2 + 0.0000012T^3.$$

The heat of combustion of methane to form gaseous CO_2 and liquid H_2O is 212400 according to Thomsen, and 212800 according to Berthelot, mean 212600. The heat of formation of liquid water we have shown in a previous paper to be 68470 at 0°C ., or 68330 at 18° . Using the heat of combustion of graphite, which we have already taken from the work of Pring and Wallasch, we find for the formation of methane from its elements $\Delta H_{291} = -18300$, and from the equation for ΔF , $\Delta H_0 = -16300$, and $\Delta F^\circ = -16300 + 6.6T \ln T + 0.0008T^2 - 0.0000002T^3 + 1T$. Measurements of equilibrium in the reaction were made by Mayer and Altmayer.

These authors obtained a higher yield of methane from amorphous carbon than from graphite, but in the latter case a true equilibrium was reached, whereas in the former the equilibrium continually changed owing to the gradual transition from amorphous carbon to graphite. The ultimate equilibrium was the same as that obtained directly from graphite. We shall give in Table V the various results obtained by Pring and Fairlie without distinguishing between the different varieties of graphite which they used. The first column shows the absolute temperature, the second the equilibrium constant $p_{\text{CH}_4}/p_{\text{H}_2}^2$, and the third the corresponding value of I . The first value given represents the average of the measurements of Mayer and Altmayer at 823°A with amorphous charcoal, which was covered with a catalyzer of nickel or cobalt and was presumably graphitized in part.

TABLE V.

T.	K.	I.	T.	K.	I.
(823)	(0.64)	(-24.2)	1673	0.00103	-26.4
1473	0.00244	-25.9	1673	0.00089	-26.1
1548	0.00147	-25.8	1673	0.00089	-26.1
1573	0.00146	-26.0	1723	0.00075	-26.1
1573	0.00158	-26.2	1773	0.00077	-26.7
1648	0.00100	-26.1	1848	0.00062	-27.0
1648	0.00117	-26.4			

There is evidently a slight trend of I with the temperature. This may be

¹ Mayer and Altmayer, *Ber.*, **40**, 2134 (1907).

² Pring and Fairlie, *J. Chem. Soc.*, **101**, 91 (1912). In this paper and in previous papers by the same authors the equilibrium conditions are investigated in the formation, not only of methane, but of ethylene and acetylene. However, we have regarded the experimental data, in the case of the latter hydrocarbons, as too uncertain to make complete free energy calculations desirable at present.

due to an error in the equation assumed for the heat capacity of methane but it may also be an experimental error, the possibility of which the authors themselves have pointed out, namely, an excessive yield of methane at high temperatures owing to the indirect formation of methane, during the rapid cooling of the gas for analysis, from other hydrocarbons which may be present at high temperatures. In either case it would be advisable to give a little more weight to the values at low temperatures and we may take $I = 26.0$. Hence

$$\Delta F = -16300 + 6.6T \ln T + 0.0008T^2 - 0.0000002T^3 - 26.0T. \quad (20)$$

Carbon Oxychloride.

$CO + Cl_2 = COCl_2(g)$.—In the absence of any reliable measurements of the heat capacity of phosgene we may assume it to be the same as that of ammonia. With the aid of the equations of CO and Cl_2 previously used $\Delta F = -5.5 - 0.0008T$. Between the values of the heat of this reaction obtained by Thomsen and Berthelot there is a great discrepancy. Thomsen obtains 27000 cal. and Berthelot 19000, which give, respectively, $\Delta H_o = -25000$; $\Delta H_o = -17000$. The value of Berthelot seems to be the more reliable and is in agreement with one calculated from the equilibrium measurements of Bodenstein and Dunant¹ which we are about to discuss. We shall take $\Delta H_o = -18000$, and

$$\Delta F^\circ = -18000 + 5.5T \ln T + 0.0004T^2 - 14.1T. \quad (21)$$

The value of I is obtained from determinations by Bodenstein and Dunant of the dissociation of $COCl_2$ at the three temperatures given in Table VI. From the value of I , $\Delta F^\circ_{298} = -12820$.

TABLE VI.

COMPRESSIBILITIES OF MERCURY, COPPER, LEAD, MOLYBDENUM, TANTALUM, TUNGSTEN AND SILVER BROMIDE.

BY THEODORE W. RICHARDS AND EDWARD P. BARTLETT.

Received January 6, 1915.

The compressibilities of the elements are data of great interest, in common with all the other properties of these fundamental substances. Until recently, however, they received but little attention. Six years ago, for the first time, results for a large number of elements, consistently determined by a new and adequate method, were available.¹ From these results it became clear that compressibilities, like many other properties of the elements, are highly periodic in their nature as referred to the progressively increasing atomic weights. Since that time much interest has been taken in the subject, and Bridgman,² at the Jefferson Physical Laboratory at Harvard University, and Grüneisen,³ at the Physikalisch-technische Reichsanstalt in Berlin, have both thrown further light upon it. In the main, these results have confirmed and amplified the earlier Harvard results, but there remain two or three points of difference to be explained, and, moreover, it seemed highly desirable to extend the list of elements. Hence the present investigation was undertaken with both of these aims in view. The method employed was precisely that used in preceding investigations,⁴ except that in our most accurate work the piezometer was made of soft steel instead of glass. For the details the reader is referred to earlier publications.

In brief, the method consisted in the determination of the difference between the compressibility of each substance in question and that of mercury, which was itself determined by reference to iron. The linear compressibility of iron has been absolutely determined by Bridgman. The piezometer used in the present investigation consisted of a cylindrical vessel of glass or soft steel filled with mercury, being so arranged that the

only free surface of this liquid metal was exposed in a capillary tube, which made it possible to measure very small changes of volume. The level of the mercury in this capillary tube was determined by a very finely pointed platinum wire, which completed an electrical circuit. Successive weighed drops of mercury were added in this tube, and the relation between the weight of this added mercury and the pressure necessary to compress the system exactly to the attainment of electrical contact was determined in each case. In this way, at first mercury alone was compressed in the piezometer, and the relation of the added mercury to the increasing pressure was found. Subsequently, each other substance in turn was completely immersed in the mercury, and the operation repeated. Obviously, if the immersed substance had the same compressibility of mercury, a curve precisely similar to the first would have been attained, but, as all the substances discussed in this paper had a less compressibility than mercury, the curves were different from that obtained when mercury alone was present, in such a sense that for a given weight of added mercury a greater pressure was necessary than with mercury alone in the piezometer. Diagrams of the two forms of piezometer will help to make the matter clear.

The glass piezometer (Fig. 1) has been described in detail before.¹ Although the steel piezometer was somewhat different in arrangement, the principle is exactly the same. It consisted of a hollow steel cylinder, K, closed at the bottom, which had been turned and bored from a heavy rod of steel. (Figs. 2 and 3.) Upon the top of this was clamped, by a powerful screw, a cover, G, containing the capillary. Below this cover was secured a little pail or capsule, J, to hold mercury, in case a lighter liquid was to be confined in the piezometer itself. This pail or capillary would, of course, be unnecessary if no liquid besides mercury were present. The contact was made by a stout, steel needle, E, with a very finely pointed platinum tip, F; it was secured above in such a way as to be rigid and unchangeable in position, centered below by a light movable bracing of wires, and was insulated from the rest of the apparatus by a thin film of mica, C. This upper portion of the piezometer is shown on a large scale in Fig. 2, since the details are important, and were the outcome of much thought and experiment.

The washer, I, sealing the joint between the cylinder and its cover gave much trouble. After various attempts with lacquered lead, copper and organic substances, we finally chose soft iron, and found that, if both surfaces of the ring of soft iron were made somewhat pointed (that is to say, the cross section of the ring made of a very elongated "diamond"-shape), good contact and complete closure were effected. The volume of liquid retained by this device outside of the washer, and not under

Fig. 3.—Sketch of exterior of steel piezometer when assembled.

quantitative compression was computed, and due allowance was made for it.

The pressure gauge was an absolute one, consisting of a perfectly cylindrical piston or plunger exactly fitting into an equally cylindrical hole just 0.0002 cm. larger in diameter, which communicated with the pressure pump. The apparatus had been made especially with unusual care by the Taft-Pierce Co., of Woonsocket, and had been very carefully studied and verified in all its details in an earlier research carried out by one of us in common with Dr. J. W. Shipley, as yet unpublished. Careful measurement of the piston gave us its area, to which was added half the area of the very thin ring of lubricant around it, and it was weighted with standardized weights by means of an oscillating carriage. For approximate preliminary observation of the pressure, a Bourdon gauge also was attached to the system. The pressure was applied by a Cailletet pump of the usual type, capable of giving 1000 atmospheres, and was transmitted to both of the gauges and the piezometers by castor oil, according to the recommendation of the Earl of Berkeley. The unit of pressure adopted is the megabar (or megabarie), which has been suggested on various sides and has now received international sanction.¹ It is the pressure of a megadyne per square centimeter, and is 1.3% less than an "atmosphere" or 2.0% more than 1 kg./cm². The mercury contact was indicated by a delicate galvanometer.

The substances studied were copper, iron, lead, mercury, molybdenum, tantalum, tungsten and silver bromide. The bar of copper was of pure commercial electrolytic material, and had been thoroughly hammered and turned. The iron had been several times hammered, in order that the pores which sometimes exist in iron should have been closed, and likewise annealed and turned to regular shape. It had been smelted by the American Rolling Mill Co., and contained 0.05% of impurity. The molybdenum, tantalum and tungsten were also each in a very compact condition. They were loaned through the kindness of Dr. W. R. Whitney of the General Electric Company, and were doubtless of high degree of purity. The silver bromide had been prepared in this laboratory, and was the same as that used five years ago by one of us with the collaboration of Grinnell Jones.² The mercury was carefully purified by orthodox methods.

The chief measurements were made as nearly as possible over the range from 100 to 500 megabars, the weight of added mercury, w , and the pressure, p , being carefully observed. These data were corrected, as indicated below, precisely to the pressure range just mentioned. In each case the

¹ *Rapport Internat. Cong. Phys.*, Paris, 1, 100 (1900); see also Richards and Stull, *Loc. cit.*, 1903; Guillaume, "Les récent progres des Syst. Métrique," Paris, 1907.

² Richards and Jones, *THIS JOURNAL*, 31, 158 (1909).

half-way point, at 300 megabars, was taken also, but since these values are only of subordinate interest, they are merely averaged and summarized in the tables below, at the end of each series. They not only verified our work over the larger range, but also served the useful purpose of determining approximately the changing pitch of the curve, dw/dp , over the whole length—an outcome which made it possible to correct each initial reading exactly to 100 megabars, and each final reading exactly to 500 megabars. Evidently the average pitch, dw/dp , over the whole range is (except with very compressible substances) about that of the tangent to the curve in the middle (at 300 megabars). The average pitch over the first half corresponds closely to that of the tangent at 200 megabars, and that over the second half corresponds closely to that of the tangent at 400 megabars. The pitch at either the beginning or the end of the curve, therefore, is found by respectively adding to or subtracting from the mean value of dw/dp over the whole range, the difference between the pitches of the first and second halves of the curve, because this difference corresponds to the change in dw/dp caused by a change of pressure of 200 megabars. This method is not very exact, because its basic assumption that dw/dp varies linearly with the pressure is not quite true; but it is near enough to correct small divergences at either end of the scale as accurately as the experimental results warrant. In the case of compressible substances like water, the pitch of the curve at each end must be experimentally determined; such determinations are recorded in some cases below. The temperature was always exactly 20.00° ($\pm 0.002^\circ$) maintained by a very accurate thermostat.

The results were all calculated for exactly the range 100–500 megabars, according to the following equation:

$$\beta = \frac{(w - w' - mK)D}{5429.0 W} + \beta',$$

in which w is the weight of mercury added in the special case, and w' that added when mercury alone is present; m the additional weight of mercury needed for the range 100–500 megabars when one gram of another liquid is substituted for an equal volume of mercury, and K the weight of the other liquid; W the weight of substance and D its density; β and β' represent the compressibility sought and that of mercury, respectively.

The first step toward this, as well as towards any other work with such a piezometer, is the compression of the instrument filled with pure mercury, of which it contained 767.0 g., under atmospheric pressure. The following table recounts a series of such compressions—it shows that under 500 megabars pressure it contains about 768.3 g., the gain for 400 megabars being recorded accurately in the table below:

TABLE I.—THE COMPRESSION OF MERCURY IN STEEL.

Range. Megabars.	Hg added.	Hg cor. 100-500 megabars.	Other data necessary.
97.5 — 500.3	1.0477	1.0384	W = 767.0
109.0 — 503.9	1.0247	1.0382	
109.0 — 499.1	1.0123	1.0383	D = 13.546
108.9 — 500.2	1.0158	1.0388	
100.0 — 300.0	(0.5227)		

$$W = 1.0384$$

This table shows, in the third column, the remarkable consistency of the method under favorable conditions. It shows also that a range of 400 megabars corresponds to the added weight of 1.0384 g. of mercury when the piezometer contained 767.0 g.—a compression of about 0.135%. Substituting in the above formula (where for this special case w' , m , and K are zero) we find that $\beta' = \beta + 3.378 \times 10^{-6}$. This represents the difference between the compressibility of mercury and the soft steel of the piezometer. It is subject to two slight possibilities of error, as follows: first, the possible existence of minute holes or cracks in the steel, into which high pressure might force mercury; and, secondly, the possible slight change of form of the meniscus under pressure. If with Bridgman¹ we assume the compressibility of this steel to be 0.588×10^{-6} at 20°, the compressibility of mercury is shown by our experiments to be 3.966×10^{-6} over the range 100-500 megabars in question—a value which is probably the maximum.

Another method of using the piezometer fortunately gives us the means of entirely avoiding the second of the above-mentioned difficulties, and causes the first to affect the result in an opposite sense. This method is to immerse a somewhat rounded bar of pure iron into the piezometer, making a new series of determinations of the relation of increasing mercury to increasing pressure and calculating the results from the difference between the outcome of the two series of experiments. According to this procedure all defects in the piezometer are eliminated, occurring in both series. Results of a second series of experiments thus planned are given in Table II; a bar of soft, pure iron already described, was placed in the piezometer, displacing 20.015 cc. of the mercury; and the same determinations were made again. The preliminary trials, which served to acquaint the experimenters with the method and to determine the amount of mercury to be added in each case, are omitted, as in the table above. With exceptions of this sort, all the results in all the following tables were consecutive.

It appears from the first table that the amount of mercury added between 100 and 500 megabars, when mercury alone was present, was 1.0384, but from the second table that this amount was only 0.6758 when the

bar of iron was immersed in the mercury—the difference between being 0.3626. This weight of added mercury occupied a volume of 0.02667 cc. at the highest pressure concerned, a volume which corresponds to the difference between the compression of 20.015 cc. of iron and exactly the same bulk of mercury, due to the addition of 400 megabars pressure. From this it is easy to calculate that the compressibility of mercury over this range must be 0.00000334 plus that of the pure iron.

Now Bridgman has determined, with great care, the compressibility of soft steel ("Bessemer screw-stock") under high pressures, and found that this compressibility is not appreciably affected by increasing pressure up to 10,000 atmospheres, as, indeed, one would expect because of the great internal pressure of the substance. His values in terms of the kg./cm². standard were 0.000000583 at 10° and 0.000000601 at 50°,¹ or 0.000000588 at 20°. In a recent investigation of Grüneisen, two different specimens of iron (having the densities 7.83 and 7.82, respectively) gave values between 0.000000585 and 0.000000633, determined by an indirect method depending upon the theory of elasticity.² In view of these facts, it seems to be fairly safe to assume (especially because the compressibility even of soft steel is probably slightly less than that of iron) that the compressibility of this latter metal at 20° is very near 0.00000060, if the pressure is registered in kilograms per square centimeter.³ Calculated in terms of the megabar standard, this becomes 0.00000061; and if this value is added to the difference between the compressibilities of mercury and iron (namely, 0.00000334), we find that the average compressibility of mercury over the range between 100 and 500 megabars

¹ Bridgman, *Proc. Amer. Acad.*, **47**, 366, 367 (1911).

² Grüneisen, *Ann. phys.*, **33**, 1257 (1910).

³ The early determinations of this value published by one of us in conjunction with F. N. Brink (*Pub. Carnegie Inst. Wash.*, **76**, 45 (1907)) made no pretensions to great accuracy. On page 52, in conclusion, the following statement is made: "Hence these results are to be considered merely as preliminary ones, worthy of publication because they exemplify the working of an efficient arrangement of apparatus, as well as because they confirm essentially the work of others on this subject." They yielded a result for iron distinctly lower than the results of Bridgman and Grüneisen. For suggestions as to the cause of the error, see pages 48-49 of the original paper; also Bridgman, *Ibid.*, p. 368.

is 0.00000395. This may be looked upon as the minimum value; and the average 0.00000396 of this and the maximum value (0.000003966) previously mentioned may be taken, with very slight probability of error, as the true compressibility of mercury. On the kg./cm². basis, this becomes 0.00000388, and on the "atmosphere" basis, 0.00000401. This is especially interesting and important because no other determination of modern accuracy over this pressure range seems to have been made. Bridgman's results at high pressure are admirable; but his method is not satisfactory at low pressure, and his results below 1000 atmospheres were merely extrapolated. It is interesting to note, nevertheless, that our result is in fairly close agreement with the results of Bridgman for mercury as extrapolated to our pressures. At 22° Bridgman found the change in volume between one and two thousand metric atmospheres to be 0.00377; for the third thousand, 0.00364; for the fourth thousand, 0.00353; for the fifth thousand, 0.00337; for the sixth thousand, 0.00324, as the mean of two series of determinations. Bridgman carried the work to higher pressures, but these do not concern us. The decrease in the compressibility for a thousand metric atmospheres is seen to be on the average nearly 0.00000013. Extrapolating to 300 atmospheres, the value becomes 0.00000391 per metric atmosphere, and correcting this to 20° (from Bridgman's figures at 0°) and then to the megabar standard, we obtain the value 0.00000398 for the compressibility of mercury, which is perhaps as near as could be expected (considering the extrapolation) to our value 0.00000396. Therefore, this latter value will be assumed in the rest of the present paper as the true average value over the range from 100-500 megabars.

Before proceeding to the determinations of the compressibilities of the several metals, a table should be given recording the constant for the glass piezometer, which was used in some cases. The glass piezometer, while it gives accurate results if quickly compressed and always read after exactly the same length of time (as soon as the heat of compression has been dissipated) shows marked hysteresis when the pressure is long continued. The determinations given below are all made under the same conditions, and the hysteresis-effects will be discussed in another connection later. The glass apparatus contained 385.28 g. of mercury.

TABLE III.—MERCURY IN GLASS.

Range. Megabars.	Hg added.	Hg cor. 100-500 megabars.	Other data necessary.
99.0 — 503.7	0.2498	0.2470	
110.2 — 509.8	0.2478	0.2481	
102.7 — 503.5	0.2474	0.2471	
503.7 — 150.4	0.2171	0.2459	W = 385.28
509.8 — 90.6	0.2580	0.2462	D = 13.546
100.0 — 300.0	(0.1256)		
Average = w = 0.2469			

The difference between the compressibility of mercury and glass over the range from 100–500 megabars is 1.60, as calculated from the above results. Therefore, the compressibility of the glass must have been 2.35×10^{-6} . This is about the usual compressibility of soft glass.

It was necessary also in some cases, in order to prevent the substance from being attacked by the mercury, to surround the former with water—an expedient possible in both forms of piezometer, as may readily be seen. For this purpose it was needful to know exactly the difference between the compression of a gram of water and an equal bulk of mercury over the range 100–500 megabars; this was found to correspond to 0.2069 g. of added mercury, since 55.08 g. of water required 11.395 g. of added mercury, as a mean of many trials.

After these preliminaries, tables giving the data for the several other solid substances are now to be given.

	Average $= w = 2.1465$				

The data in the preceding tables yielded upon suitable calculation the following results, which represent the averages of all the determinations in each case. It should perhaps be noted that the two values for $\beta - \beta'$ for tantalum, -3.45×10^{-6} and -3.36×10^{-6} are the most widely discrepant of all the values. This was doubtless because so small a quantity of tantalum was used—less than 2 cc. The first (more directly found) value may be given twice the weight of the second. In the case of copper on the other hand, where two entirely separate sets of observations were made, the values for $\beta - \beta'$ were, respectively, 3.18×10^{-6} and 3.21×10^{-6} . In both cases study of the data will show that this agreement is as good as could reasonably be expected, considering the quantities of materials used and the extremely minute values to be measured.

Attention is called to the extremely small value of the compressibility of tungsten—the smallest, perhaps, of any substance which has thus far been measured.

FINAL RESULTS.

Temperature = 20.0°.

Calculated upon the megabar standard.

Substance.	$(\beta - \beta') \times 10^6$.	Compressibility $\times 10^6$. (Average over range 100–500 megabars.)
Copper.....	—3.20	0.76
Iron (standard).....	—3.35	(0.61)
Lead.....	—1.61	2.35
Mercury.....	0	3.96
Molybdenum.....	—3.49	0.47
Tantalum.....	—3.42	0.54
Tungsten.....	—3.68	0.28
Silver bromide.....	—1.26	2.70

It will be seen that the values given in the first column of figures agree quite as closely as could be expected with the values given for $\beta - \beta'$ by the early Harvard work. Thus the old value for copper was -3.25 ;¹ that for iron -3.385 ; that for lead (only a single experiment) -1.55 ; and that for silver bromide -1.20 , all reduced to the megabar standard. The reason why the compressibilities formerly computed from these values differed considerably from those in the last column above is simply because β' was taken as 3.79×10^{-6} in the old work (the best value then available), whereas in the present work it is taken as 3.96×10^{-6} —a difference of 0.00000017, which must be added to all the old values in order to make them correspond to the present knowledge concerning mercury. A more extensive discussion of this connection will be given in another place.

It is interesting to note also that the values given above are in excellent accord with the results of Grüneisen, as indicated in the papers already mentioned. His average value for copper is 0.74 to 0.78; for iron 0.59

¹ *Pub. Carnegie Inst. Wash.*, 76, 44 (1907).

to 0.64; for lead (which is too soft to give good results by his method), 2.0 to 3.2. Thus in each case our values lie between his extremes. The other substances were not studied by him, and there are two among them (namely, tantalum and tungsten) which have never before had their compressibilities determined, so far as we know. It is especially satisfactory to have the apparent inconsistencies of the earlier results adequately explained and removed.¹

We are greatly indebted to the Carnegie Institution of Washington for generous support in this investigation.

Summary.

This paper describes careful determinations involving the compressibilities of eight substances, of which two had apparently never been studied before, namely, tantalum and tungsten. The method which has been used for over ten years by one of the authors was modified by the construction of the piezometer of steel instead of glass. This change has the advantage of avoiding the hysteresis of glass under high pressure. The results show, however, that the method of manipulation used in the earlier work had overcome this difficulty and that the earlier results were quite as satisfactory and accurate as they were supposed to be at the time. The difference in the final values of the compressibilities is due chiefly to the change in the assumed compressibility of mercury, which is now referred to a better new absolute value for iron (0.00000061) rather than to earlier less accurate work. The compressibility of the various substances, at 20° (expressed in the megabar standard, multiplied by a million) were found as follows: Copper 0.76, lead 2.35, mercury 3.96, molybdenum 0.47, tantalum 0.54, tungsten 0.28, silver bromide 2.70. In each case the range of pressure was between 100 and 500 megabars. The outcome is as consistent as could be expected with the work of Bridgman and Grüneisen, and previous discrepancies are explained. Especial attention is called to the very small compressibility of tungsten.

THE MEASUREMENT OF THE FREEZING-POINT DEPRESSION OF DILUTE SOLUTIONS.

By LEASON H. ADAMS.

Received December 20, 1914.

The present paper is a description of a method of determining the freezing-point depression of dilute solutions, by the use of which one is enabled to observe the equilibrium temperature with an uncertainty

¹ Attention is called to the interesting compilation by W. Schut entitled "Piezo-chemie der Gecondenseerde Systemen" (Utrecht, 1912) when some of these matters are discussed.

no greater than 0.0001° and to measure the equilibrium concentration with commensurate accuracy. Results are presented for the non-electrolyte mannite and for the salts KCl and KNO_3 , all at concentrations ranging from about 5 to 100 millimolal; the latter are shown to agree very well, at the lowest concentrations, with the degree of ionization derived from conductance measurements.

The characteristic property of an electrolyte in aqueous solution is its degree of ionization, or its mol number; the latter, which is directly related to the former, is the relation of the apparent concentration—as deduced from the freezing point (or vapor pressure or osmotic pressure) of the solution by means of the laws of the perfect solution—to the concentration calculated on the basis of the respective weights of solute and solvent present. The mol-number may also be derived from the conductance ratio, on the basis of certain assumptions, of which the most important are: (1) that the equivalent conductance (Λ_0) of the ions does not vary with the concentration, except in so far as the fluidity of the solution varies; (2) that an accurate value of Λ_0 can be obtained by extrapolation from the measured conductances, and that the influence of change of fluidity upon this Λ_0 value can be satisfactorily allowed for. The usual interpretation of the results obtained from any of the methods of measurement involves the assumption that the only forms in which the substance exists in the solution are the un-ionized molecules and the ultimate simple ions into which they dissociate at extreme dilution.¹

Altogether then, the mol-numbers derived from the conductance ratio are trustworthy only when the uncertainties involved in the above assumptions are unimportant—in other words, only when the concentration is as small as 0.1 formal, or even less. Of the other methods, the one susceptible of the highest accuracy at the present time is the measurement of the freezing-point depression; but unfortunately it is a matter of some difficulty to measure the freezing point of such dilute solutions with sufficient percentage accuracy to admit of a really satisfactory comparison of the mol-numbers so derived with those derived from the conductance of such solutions. For example, a 0.01 formal solution of KCl freezes at -0.0361° , so that an error of only 0.001° in the equilibrium temperature corresponds to an error of 3% on the observed lowering, and accordingly to an uncertainty of 6% in the degree of ionization derived therefrom; while further uncertainty will of course result if the concentration of the solution in equilibrium with ice at the freezing point is not known with sufficient accuracy—and lack of exactness in this respect has been a frequent source of error in the past. But for a trustworthy comparison of the mol-numbers derived in the two ways, the degree of ionization derived

¹ With regard to these matters, see especially A. A. Noyes and K. G. Falk, *THIS JOURNAL*, 32, 1011-15 (1910); 34, 454-60, 487-9 (1912).

from the freezing point should be known within 1%, even for the solutions ranging down to 0.005 formal; this degree of accuracy necessitates the determination of the freezing-point depression to 0.0001° , and a commensurate exactness in the equilibrium concentration. A method of achieving this accuracy is presented in the following pages; but before describing it, we shall refer briefly to some of the best recent work in this field.

During recent years the determination of the freezing-point depression of aqueous solutions has been undertaken by a large number of investigators, with a steady improvement in apparatus and technique. The principal improvements are two: the substitution of a device for measuring directly the depression of freezing point, in place of the mercury thermometer which measured the freezing point only and that with a precision probably not better than 0.001° ; the abandonment of the old Raoult method of supercooling a solution of known concentration, which involved a correction for change of concentration due to separation of ice, as well as an uncertainty in the equilibrium temperature.

As a temperature-measuring device for accurate work, mercury thermometers were abandoned in favor of compound thermoelements by Hausrath,¹ Osaka,² Jahn,³ and Flügel;⁴ also by Bedford,⁵ who employed a differential platinum resistance thermometer. The first one to improve on the original Raoult supercooling method was Roloff,⁶ who, acting upon a suggestion of Nernst, determined by analysis the composition of solutions in equilibrium with a large amount of ice which had been frozen out of the solutions. Jahn,⁷ Flügel,⁴ and Roth⁸ later made use of this same method, while Walker and Robertson,⁹ and also Richards¹⁰ mixed the salt solutions directly with ice separately frozen and placed in the freezing-point vessel. This last procedure is to be preferred because it minimizes the chance of error from a possible solubility or inclusion of the salt in the ice.

The data of Jahn and of Flügel are probably the most generally reliable, but even they are not entirely beyond question; because, so far as one can gather, neither investigator appreciated the importance of homogeneity in wire used for thermocouples or of the necessity of special tests for, and

the removal of, the heterogeneous portions of the wire so used. It is also open to question whether their respective potentiometer outfits were of a type sufficiently free from parasitic electromotive forces to insure the accurate reading of small fractions of microvolts. In other words their temperature measurements may not be so accurate as the published data would suggest. This matter will be reverted to later.

The Method.—The essentials of accurate freezing-point determinations are substantially as follows: (1) Rapid and certain attainment of a (practically) stationary temperature equilibrium; (2) accurate and convenient measurement of the temperature, preferably of the freezing-point lowering directly by means of a differential method; (3) determination with sufficient exactness of the concentration of the equilibrium solution. These conditions were realized: (1) by thoroughly mixing the solution with a large amount of broken ice by means of a specially designed stirrer; (2) by measuring directly, with a multiple-junction thermoelement and sensitive potentiometer outfit, the difference between the equilibrium temperatures, ice-solution and ice-water; (3) by analyzing the equilibrium solution by means of a Zeiss interferometer¹ used practically as a zero instrument. We shall now proceed to describe the apparatus in detail.

Temperature Measurement.

The Thermoelement.—Copper and constantan were selected as the thermoelectric pair since in magnitude of thermoelectric power, homogeneity, permanence, and ready availability this is, at present, the most generally suitable couple for use at low temperatures. The copper wire used was No. 36 B. S. (0.15 mm.), the constantan No. 30 (0.25 mm.) both double silk covered.² The element was made up of 50 couples connected in series and all enclosed at each end in a single glass tube of about 7 mm. outside diameter.

Construction of the Element.—Full details of construction are presented since they may be useful to any one desiring to make a similar element. From a sufficient length of copper, and of constantan wire which had been carefully tested for homogeneity,³ the 50 pairs of wires were cut off and covered with shellac; when dry they were bared of insulation for 2 or 3 mm. at each end, and hard-soldered together as shown

¹ In the case of electrolytes the electrical conductance could well be employed as a means of determining the equilibrium concentration.

² The "Ideal" wire made by the Electical Alloy Co., Morristown, N. J., is the best constantan wire for thermoelements which we have used. Almost any copper wire will be found suitable. Instead of silk-covered wire the enameled wires now obtainable possess certain advantages, namely that the insulation is thinner and will stand more handling and a higher temperature without deteriorating.

³ See W. P. White, *THIS JOURNAL*, 36, 2296 (1914). The most convenient method of testing a small lot of wire is to draw it through a narrow U-tube, preferably of metal, immersed in boiling water. It is not necessary to test the copper wire.

diagrammatically in Fig. 1, care being taken that the finished joints are free from sharp points or projections.

The best method of hard-soldering such small wires is to use a tiny gas flame (8 mm. long) issuing from a glass tip with a hole 0.2 mm. in diameter at the end; the solder consists of a mixture of 3 parts of brass to 1 of silver, and (anhydrous) borax glass is used as a flux. The whole operation is rapid and easy if one is careful to use small quantities of both borax and solder—not more than 0.5 mg. of borax and 3 mg. solder for each joint.

Fig. 1.—Diagram to show arrangement of the copper and constantan wires in the thermoclement. The wires are joined in two groups of 5 couples (25 in the actual element); the terminal (copper) wires of which may be connected either as at X or at Y, thus enabling one to throw the two halves either in series or in opposition.

When soldered the junctions are covered with an insulating varnish of which the best is a coating of hard rubber applied as follows: Enough precipitated sulfur, or still better insoluble sulfur, is stirred up with rather thick rubber cement (pure gum rubber dissolved in benzene and carbon disulfide) to equal 20–25% of the solid rubber. The junctions are dipped in this mixture and, after drying in the air, maintained at 140° for 15 hours or longer.

The element is now ready to be assembled and enclosed. As may be seen from Fig. 1 the wires are joined together in two halves with four lead-wires, by means of which the two halves may be connected either in series or in opposition. This arrangement allows the element to be tested at any time for electrical leaks or short circuits, since if one end is placed in ice while the other end remains at room temperature, the electromotive force at Y (Fig. 1) will be zero only when there are no internal short circuits or leaks. Measurement of the resistance of the two halves and of

the insulation resistance¹ between them will serve the same purpose and is especially useful during the final assembling and enclosure of the wires. Experience has demonstrated the necessity of constantly testing in this way the element at all stages of construction in order to detect and obviate all internal leaks or short circuits.

In binding the wires together it is desirable to distribute the junctions in the form of a cone about 4 cm. long and to make a compact bundle of the wires by wrapping with fine silk thread. The necessary stiffness in the central portion is secured by binding in a small brass rod, bent to shape, extending about 3 cm. beyond each bend. Each end is embedded in fused naphthalene in a glass tube of as small diameter as practicable; and finally the central portion is paraffined (in order to exclude moisture, which may cause the insulation resistance to decrease beyond the margin of safety) and wrapped with silk ribbon. It is advisable to protect the lead-wires from possible breakage, especially at their point of exit, by twisting them together with a thin piece of cord.

Potentiometer.—A potentiometer² of careful design was used, by means of which, in conjunction with a sensitive Weston galvanometer, a precision of 0.1 microvolt was readily attained. The whole potentiometric apparatus was protected from leakage, etc., by two equipotential shields,³ so that even in damp weather the total leakages and parasitic electromotive forces never exceeded 0.5 microvolt. The residual leakage, etc., was, however, continuously compensated for by means of the usual eliminating switch. The lowest decade consisted of steps of 10 microvolts each; units and tenths of microvolts were read directly with telescope and scale, the sensitiveness of the galvanometer being kept adjusted so that 10 microvolts gave a deflection of exactly 10 divisions on the scale.

Calibration of the Element.—The thermoelement was calibrated against a 24-junction element previously calibrated at the Bureau of Standards to 0.001° between 0° and 50°. Comparisons with the standard element were made in a well-stirred kerosene bath at 10°, 20°, and 30°; from these readings an equation was calculated which expresses the relation between the temperatures as determined by the standard element and the microvolts registered by the unknown element.⁴ By differentia-

¹ It is convenient to do this on the potentiometer itself.

² This potentiometer has been described by W. P. White in *Z. Instrumentenkunde*, 34, 79 (1914).

³ A full discussion of choice of potentiometers, mode of shielding, and other points in connection with potentiometer installation, is given in recent papers by W. P. White, *THIS JOURNAL*, 36, 1856, 1868, 2011 (1914).

⁴ The readings of a copper-constantan couple at these low temperatures are reproduced equally well by a cubic equation of the form $E = At + Bt^2 + Ct^3$ and by an exponential of the form $E = At + B(1 - e^{Ct})$. At higher temperatures the latter is preferable. Compare L. H. Adams, *J. Wash. Acad. Sci.*, 3, 469 (1913).

tion of this equation, the gradient at 0° —that is the number of microvolts per degree at 0° —was derived. This gradient changes by only $1/400$ of itself per degree, and therefore small temperature differences may be accurately obtained from the readings in microvolts simply by multiplying by the reciprocal of the gradient—in the present instance 0.0005198° per microvolt at 0° . As the temperature difference increases, however, the departure from linearity becomes appreciable, being proportional to the square of the temperature difference; thus at temperatures of -0.3° , -0.4° and -0.5° the error introduced by the assumption of strict linearity is 0.0001° , 0.0002° and 0.0003° , respectively. The temperatures obtained by multiplying the reading in microvolts by the factor above mentioned have been corrected, therefore, by adding the appropriate small amount.

Freezing-point Apparatus.—The freezing-point vessels consist essentially of two exactly similar vacuum jacketed silvered jars *A* and *B* (Fig. 2), arranged so that they are completely surrounded by melting ice. One end of the thermoelement dips into *A*, which contains ice and water, the other into *B*, which contains ice and solution; thus, by means of this arrangement the thermoelement records directly the freezing-point lowering produced by the salt. Each jar is closed with a cork-stopper, previously thoroughly soaked in hot paraffin, which serves also to hold the thermoelement and pipet in position. The jars sit in cylindrical tin cans, which are supported in a large sheet metal pot, covered with a thick layer of wool felt, and nearly filled with ice. The double lid, likewise covered on the top with felt, is also filled with ice. This arrangement secures the great advantages: (1) that the maximum temperature gradient to which the thermoelement is exposed does not exceed 1° ; (2) that the melting of the ice, and consequently the change of concentration of the solution, and hence of freezing point, is very slow. Indeed the freezing point of the solutions, even when left unstirred, did not change by more than 0.001° in an hour.

Mode of Stirring.—Thorough admixture of solution with the ice is absolutely essential; this is secured by the similar stirrers *S, S*, which are shown more in detail in Fig. 3. This stirrer is really a circulating pump, its function being to withdraw liquid from the bottom of the vessel and discharge it over the top of the ice, whence it flows downward through the ice to the bottom again; relatively few strokes are sufficient for the attainment of complete mixing and cooling. The pump is of brass, heavily gold plated. The barrel *E* (Fig. 3) is a half cylinder open at both ends except for the screen at the bottom which serves to prevent ice from entering the stirrer; this barrel is held in position in the freezing vessel by means of the thin strips *H* which act as springs. The bucket-shaped piston *D*, which is a fair fit for the inside of the barrel, is moved up and

Fig. 2.—Freezing-point apparatus. Two exactly similar vacuum-jacketed vessels (A, B) are surrounded with cracked ice contained in a large pot which is well insulated by a layer of wool felt. The double lid is also filled with ice and covered with felt. Jar A contains finally about 400 g. ice and 600 g. water; jar B the same respective amounts of ice and solution. The liquid in each jar is stirred by means of the similar hemicylindrical stirrers S, S which, when actuated by the glass rods R, R, pump liquid from the bottom of each jar and discharge it at the top over the ice. The difference in temperature between ice-water and ice-solution is measured directly by the differential thermoelement of 50 junctions and sensitive to 0.0001° . Two thermoelement lead-wires (there are really four) are shown at L, L. When temperature equilibrium is attained a sample for analysis is withdrawn by means of the combined pipet and funnel P, which also serves to introduce water and solute into jar B. When equilibrium is attained in both A and B, the temperature difference to 0.0001° is measured directly by means of the 50-junction differential thermoelement (T; its terminal wires are L, L); the concentration is determined on a sample withdrawn through the pipet P.

down by means of a glass rod fastened to the central stem, G; it is open at the top, and its bottom is slotted as shown in the figure. These open

Fig. 3.—Drawing in plan and elevation of stirrer; to show mode of operation. The stirrer, made of brass heavily gold-plated, is really a circulatory pump with a hemicylindrical barrel. In this barrel, E, open at both ends, the bucket-shaped piston D slides easily; D is open at the top and slotted at the bottom, the slots being closed by the clapper C when D is raised, but open when D is lowered. The clapper C is kept in alignment by the bearing F which slides on the square stem G. The stirrer is operated by means of the glass rod R (Fig. 2), and held in place in the freezing-point vessel by the springs H, H.

spaces are just covered by the solid portions of the clapper-valve *C* which is held in alignment by the small hollow barrel *F* sliding on the stem *G*. *It is thus evident that when the bucket with clapper in place is pushed down through liquid contained in the barrel, the pressure of the liquid from below will force the clapper to rise and allow liquid to flow through; but when the bucket is raised the clapper is held down, and hence liquid is lifted up and out over the top of the barrel. The piston was made bucket-shaped in order to avoid any considerable leak and to have at the same time a loose and easy fit. These stirrers proved to be very efficient; each stroke circulated approximately one-half of the liquid in the vessel, and consequently but little stirring was required.*

Analysis of the Equilibrium Solution.—Samples for analysis were withdrawn by means of the sampling pipet *P*, which served also for the addition of water or of solute (in the form of a concentrated cooled solution). The concentration of the solutions was determined by what is practically a zero method; namely, a Zeiss interferometer was used to compare this unknown solution with known solutions of very nearly the same concentration, and hence served practically as a means of interpolation over a small range. In the case of mannite a series of known solutions was compared with water, and the readings plotted; the unknown solutions were also compared with water and their concentration was derived by interpolation on this curve of the readings of the instrument. The former way is in general preferable, since there is then less chance of mistaking the proper band for comparison.

With the instrument used in this work¹ one can bring the upper and lower bands into conjunction with an uncertainty of not more than 1 division on the scale. It is thus possible, with the 40 mm. chamber, to determine the percentage composition of a solution of a colorless salt or non-electrolyte to within 0.0002—that is to within two parts of salt in a million of water. The attainment of this degree of certainty demands some experience with the instrument; this matter will not be discussed further here, since it forms the subject of another communication.

Experimental Procedure.—The vacuum-jacketed jars are set in position in the large can and surrounded by cracked ice; the stirrers are set in place and about 500 cc. of cooled distilled water poured into each jar. Ice,² in pieces about the size of an almond and previously washed with distilled water, is then put into each vessel until the half not occupied by the stirrer is filled; this required about 500 g. The water level is then adjusted so as to be about 5 mm. above the top of the stirrer. The paraf-

¹ The Water Interferometer manufactured by Carl Zeiss, Jena.

² Ordinary artificial ice was used. This ice was always very pure, being made from distilled and filtered water. Moreover, as will be explained below, any small residual impurity in the ice would be without prejudicial effect on the final results.

finer cork stoppers are then placed on the jars, one leg of the thermoelement pushed into each jar and the ice-filled cover placed in position¹ on the outer can. The narrow tube of the sampling pipet is then shoved through a hole in the cover and down into jar *B*.

The apparatus is then allowed to stand for two or three hours with occasional stirring in order that all the various parts in the interior may cool down to nearly zero; after which both sides are stirred until a constant thermoelement reading is obtained. This so-called "zero" reading² is noted, and a sample of about 50 cc. withdrawn from jar *B* and preserved in a Jena glass flask sealed with a sheet of tinfoil tightly crimped about the neck of the flask. The purpose of this initial sample is to determine a "concentration zero" reading on the interferometer. The desired amount of solute dissolved in enough ice-cold water to make up the exact volume of liquid previously withdrawn is then added; both sides are again stirred at intervals until temperature equilibrium is attained. In order to rinse the pipet *P*, it is half filled with solution by suction and given a gentle rotary shake, after which process the solution is returned to the vessel. A few strokes of the stirrer suffices to bring about a condition of equilibrium which, with occasional stirring, does not change in the course of several minutes. The temperature is now read and a sample of 50 cc. for analysis withdrawn by means of the pipet *P*. More salt may now be introduced for a new determination. From each temperature reading the "zero" temperature reading is subtracted and similarly from each concentration reading is deducted the "zero" concentration reading—that is, the reading on the interferometer of the zero sample against the water from which the standard calibration solutions were made up.

Usually a series of five or six determinations was carried out with one set-up of the apparatus; but it is to be noted that the several pairs of readings constitute a series of independent observations. That there is no serious systematic error follows from the smallness and constancy of the two zero readings; moreover, any factor prejudicial to the result would have increased *both* of these readings and hence would be substantially eliminated. Nevertheless, it was thought desirable to have a direct check on the accuracy of the method; for this purpose a series of determinations were made with dilute solutions of the non-electrolyte mannite. These results, together with those obtained with the salts potassium nitrate and potassium chloride, will now be presented.

¹ This was facilitated by guiding rods (not shown in Fig. 2).

² This reading was usually about 1 microvolt, but probably does not indicate a corresponding difference in temperature (0.0005°) between the two vessels. It undoubtedly represents the summation of several small electromotive forces. The analogous concentration "zero" reading was never greater than 3 divisions on the interferometer.

Experimental Results.

Mannite.—The mannite was recrystallized from water and dried by heating *in vacuo* for several hours at 130°. Table I is a complete record of the observations. The first three columns reproduce (I) the measured equilibrium concentration ($N \times 10^3$), expressed in millimols per 1000 g. of water, and the directly measured freezing-point depression (II) in microvolts and (III) in degrees. The fourth column shows the calculated lowering as derived from the equation $N = \Delta t (1 + 0.0055\Delta t)/1.858$, the theoretical expression for the depression of a solution containing N moles per 1000 g. of water; the fifth gives the differences, in ten-thousandths of a degree, between the observations and the values so calculated. The last two columns are a similar comparison of the observed concentration with that calculated from the observed depression.

The differences are in no case greater than 0.0001°, and thus justify our expectations as to the accuracy of the method.

Potassium Nitrate.—This salt was chosen for the reason that, as shown in the compilation of Noyes and Falk,¹ there is a large discrepancy between the ionization values of KNO₃, as determined by the two methods of freezing-point lowering and conductance ratio.

The salt used was twice recrystallized from H₂O and dried by heating *in vacuo* at 150° for several hours. The results are given in Table II.

direction by an error of 0.0005° . For the sake of comparison the data of Loomis² are also included; his results are in general too low, as Noyes and Falk³ presumed. The recent measurements of Roth,⁴ made by a method identical with that used by Loomis, are so numerous that they

¹ This diagram was actually plotted on coordinate paper having a logarithmic scale in one direction.

could not well be included in the diagram; Roth's data lie very close to those of Loomis and are, therefore, presumably affected by a similar error.

just below its melting point. The observations are brought together in Table III and plotted in Fig. 5, in which are also included the data of Jahn¹ and Bedford² on this salt.

Discussion of Results.—From the observations tabulated in Tables II and III values of the formal lowering at round concentrations were obtained by graphic interpolation; these are presented in Table IV. The first column contains the concentration (N); the second, the corresponding formal lowering; the third, the mol-number (i) as calculated from the equation $i = \Delta t (1 + 0.0055\Delta t) / 1.858 N$, and the fourth, the corresponding percentage ionization γ as derived from the relation $\gamma = 100(i - 1)$.

The ionization values in Cols. V and VI are taken from the paper of Noyes and Falk;³ they are derived, respectively, from the conductance-viscosity ratio and from the weighted means of the freezing-point data on these salts available in 1910.

Comparison of Cols. IV and V shows that in the case of potassium nitrate the difference between the ionization derived from freezing point and from conductance is no greater than the experimental error at all concentrations up to 0.02 molal; this disposes of the discrepancy noted by Noyes and Falk, whose mean values for this salt are derived solely from Loomis' data which, as they considered probable, are too low. At the higher concentrations the values in Cols. IV and V diverge; this shows merely

¹ H. Jahn, *Z. physik. Chem.*, 50, 137 (1905).

² T. G. Bedford, *Proc. Roy. Soc. London*, (A) 83, 454 (1910).

³ Noyes and Falk. *THIS JOURNAL*, 34, 486 (1912).

that some of the assumptions implicit in these calculations are not fulfilled.¹ In the case of potassium chloride the agreement between the several values of the percentage ionization is all that could be desired;² this serves to demonstrate the trustworthiness of the method here described, since the mean difference between these new observations and the weighted mean—in this case of a large number of (somewhat discordant) results published by eleven different authors—is no greater than 0.0001° (or the corresponding amount in terms of concentration).

It is thus evident that by the proper choice of method and apparatus it is possible to determine freezing-point depressions with an accuracy of 0.0001° . Indeed there appears to be no inherent reason why it should not be practicable to attain a tenfold accuracy by the use of a still more sensitive differential temperature measuring device, and of a still more refined means of determining the concentration of the equilibrium solution, both of which appear from our experience to be within the limits of practicability.

Summary.

Trustworthy values of the mol-number and of the corresponding ionization value can be derived from observations of the depression of freezing point only when the concentration, as well as the temperature, of the solution in equilibrium with ice have been determined with sufficient, and commensurate, accuracy. In the work described in the preceding pages the depression was measured directly with an uncertainty of not more than 0.0001° by means of a 50-junction copper-constantan differential thermoelement (which gives 2000 microvolts per degree) and a potentiometric system which enabled the electromotive force to be read to 0.1 microvolt. A prerequisite for the attainment of this degree of accuracy is a condition of stationary equilibrium, which was secured by thorough mixing of the solution with a large quantity of ice in a vacuum-jacketed vessel completely surrounded by melting ice. The concentration of the equilibrium solution was determined by a zero method in which a Zeiss interferometer was used as a means of comparison; the sensitiveness of this method is about 2 parts of solute per million of water.

Results are presented for solutions of the non-electrolyte mannite and of the salts potassium nitrate and chloride at concentrations ranging from 0.004 to 0.1 formula weights per 1000 g. water; consideration of these shows that the method is susceptible of the accuracy claimed for it.

WASHINGTON, D. C.

¹ Cf. Noyes and Falk, *Ibid.*, 34, 488 (1912).

² Kraus and Bray (THIS JOURNAL, 35, 1412 (1913)) conclude that the value of Λ_0 for KCl is 128.3 at 18° ; on this basis the ionization values given in Col. V of Table IV should be increased in the ratio 130/128.3 and the agreement with Col. IV would then be less satisfactory.

ANHYDROUS HYDRAZINE. II. ELECTROLYSIS OF A SOLUTION OF SODIUM HYDRAZIDE IN ANHYDROUS HYDRAZINE.¹

By T. W. B. WILSH.

Received January 11, 1915.

The hydrides of the elements in the second series, Groups V, VI, and VII of the Mendeléeff periodic table have, in so far as they have been studied from this point of view, been found; (1) to be very poor conductors of the electric current; (2) to act as solvents for certain inorganic salts; and (3) to behave as ionizing solvents. Ammonia, for example, has been extensively studied by Gore,² Cady,³ Goodwin and Thompson,⁴ Frenzel,⁵ Franklin and Kraus,⁶ and Franklin.⁷

Ostwald,⁸ Hantzsch,⁹ and West¹⁰ have determined the conductivity of aqueous solutions of hydronitric acid. The action of the electric current upon ammonium trinitride in aqueous solution has been investigated by Hittorf.¹¹ Solutions of hydronitric acid and of sodium trinitride have been electrolyzed by Peratoner and Oddo¹² and by Sarvasy.¹³ In 1909 Browne and Lundell¹⁴ electrolyzed solutions of potassium trinitride in anhydrous hydronitric acid and have shown that, while the anhydrous acid is a very poor conductor of the electric current,¹⁵ the solutions of potassium trinitride conduct the current very well indeed.

Calvert¹⁶ found the specific conductivity of hydrogen peroxide to approach that of water. Franklin¹⁷ has shown that hydrogen fluoride possesses strong solvent powers.

Cohen and de Bruyn¹⁸ have shown that anhydrous hydrazine is a poor conductor of the electric current. De Bruyn¹⁹ has determined the solu-

bilities of sodium chloride, sodium nitrate, potassium chloride, potassium bromide, potassium iodide, potassium nitrate, and barium nitrate in anhydrous hydrazine at 12.5°.

The present paper contains the record of a series of experiments made upon the action of the electric current upon solutions of the hydrazo-base,¹ sodium hydrazide in anhydrous hydrazine. The results obtained have been described under the following headings: (1) preparation of sodium hydrazide, (a) preparation of anhydrous hydrazine, (b) action of anhydrous hydrazine upon sodium amide, (c) action of anhydrous hydrazine upon metallic sodium; (2) apparatus employed in the electrolysis; (3) general procedure; (4) details of experiments; (5) discussion of results; and (6) summary.

Preparation of Sodium Hydrazide.

Lobry de Bruyn² subjected metallic sodium to the action of hydrazine hydrate and anhydrous hydrazine, respectively, and obtained in the first case, a substance to which he assigned the formula N_2H_5ONa , and in the second, the mono-sodium hydrazide. No analyses are given for either product, although it is stated that hydrogen and ammonia are evolved. Later Scandola³ treated finely divided sodium, suspended in ether, with hydrazine hydrate and obtained a white explosive substance, soluble in alcohol and water, but insoluble in ether, petroleum ether and benzene; it decomposes at 58° and is combustible at higher temperatures when heated. No analyses were given. The conclusion was drawn that the substance is different from that obtained by de Bruyn⁴ and may possibly have the formula $HN-NNa$ or $NaN-NNa$.

Ebler and Schott⁵ studied the action of hydrazine hydrate on zinc and found that in absence of air there was no action. In presence of air, however, the hydrazinated zinc salt of hydrazine carboxylic acid, $Zn(O.CO.NH.NH_2)_2.2N_2H_4$ was obtained and analyzed. In 1910 Ebler and Krause⁶ prepared zinc hydrazide, to which they assigned the formula

¹ The term *hydrazo-base* for a metallic hydrazide and *hydrazo-acid* for an acid hydrazide are here suggested in order to follow the nomenclature used by Franklin in connection with the ammonia series of acids, bases, and salts. The behavior of the hydrazine series of acids, bases, and salts in anhydrous hydrazine is now under investigation in this laboratory and will be made the subject of a future communication.

hydrazine in anhydrous ether. They suggest that they may possibly have obtained small amounts of $\text{Zn}(\text{NH.NH}_2)_2$ also. The investigators suggest these methods as generally applicable for the preparation of metallic hydrazides.

While preparing anhydrous hydrazine by treating hydrazine hydrate with sodium amide Stollé¹ found that when the sodium amide was present in excess he obtained sodium hydrazide in accordance with the equation² $\text{N}_2\text{H}_4 + \text{NaNH}_2 = \text{NaN}_2\text{H}_3 + \text{NH}_3$.

Preparation of Anhydrous Hydrazine.—The anhydrous hydrazine employed in the experimental work described in this paper was prepared by dehydrating hydrazine hydrate with barium oxide according to the method of de Bruyn³ and using the very convenient apparatus described by Hale and Shetterly.⁴ The apparatus was modified, however, to the extent of having the Vigreux distilling tube jacketed and cooled by running water so as to insure a most efficient condensation during the period of reflux.

Partially dehydrated hydrazine hydrate was boiled in this apparatus for about three hours with about a 50% excess of barium oxide. The water was then removed from the Vigreux condenser, and the hydrazine was distilled under reduced pressure, in an atmosphere of hydrogen, into the container. The product was found by analysis to contain 99.7% hydrazine.

The method used for the determination of hydrazine throughout the present research was that suggested by Rimini⁵ and modified by Hale and Redfield.⁶ Methylene blue was used as indicator in all of the iodine titrations. The hydrazine was kept in small glass-stoppered bottles, the stoppers of which were lubricated with a little of the anhydrous substance. By covering the stoppers and the necks of the bottles with tin foil and holding this tightly in place with rubber bands, circulation of air around the stopper was prevented and the amount of moisture working its way into the anhydrous hydrazine was reduced to a minimum.

Action of Anhydrous Hydrazine upon Sodium Amide.—The sodium amide used was obtained through the courtesy of the Synfleure Scientific Laboratories. On analysis it was found to be satisfactory for use in this piece of investigation.

As the result of preliminary experiments performed in this laboratory in 1909 by Dr. C. F. Hale it was found that a very explosive yellow compound was obtained by treatment of sodium amide with 96% hydrazine.

The reaction was conducted in an atmosphere of hydrogen and nitrogen, respectively. In every case the product exploded before it could be analyzed. In one instance, under reduced pressure, a somewhat bluish deposit, probably of metallic sodium, was formed upon the walls of the tube as a result of the explosion.

Experiments were first performed in order to determine the amount of ammonia liberated by the action of a weighed amount of sodium amide on an excess of anhydrous hydrazine. The apparatus employed was a glass-stoppered U-tube of special construction so arranged that the sodium amide and hydrazine could be brought into contact in an atmosphere of hydrogen (purified by bubbling through alkaline pyrogallol and sulfuric acid) and the liberated ammonia driven over and absorbed in sulfuric acid. Any hydrazine that may have been carried over into the absorbing liquid was oxidized by boiling with potassium iodate. The ammonia was determined by making the solution alkaline and distilling into an excess of standard acid.

It was found necessary to use the sodium amide in finely divided form, as otherwise it will react but slowly with the hydrazine on account of a protective coating of the sodium hydrazide which forms on the surface. Action began as soon as the materials were brought into contact with each other. Gas was given off, the powder became yellow, increased in bulk and eventually went into solution in the hydrazine. If the amount of hydrazine was not too great the solution was of an amber-yellow color. If, however, the hydrazine was present in excess of a certain amount, the solution became colorless. On standing, the yellow solution in general became colorless—in a few minutes in case a large excess of hydrazine was present, but only after a long time, several months in some cases, when a small excess was present.

In the three experiments performed 0.0571, 0.0484, and 0.0482 g. of sodium amide were treated, respectively, with a relatively large excess (about 8 cc.) of hydrazine. In the first two experiments, in which the reaction was conducted in an atmosphere of hydrogen, 0.0914 and 0.1024 g. of ammonia were obtained. By far the greater part of this ammonia was liberated during the first violent stage of the reaction. In the third experiment, in which the reaction took place in an atmosphere of pure dry ammonia and in which the evolved gases were collected in a Schiff nitrometer filled with dilute sulfuric acid, 20.8 cc. of nitrogen and 16.3 cc. of hydrogen were obtained.

From these experiments it is apparent that treatment of sodium amide with hydrazine results in the liberation of ammonia, nitrogen, and hydrogen. Since the amount of ammonia formed is far greater than that obtainable from the sodium amide it is possible that the initial hydrazinolysis of the sodium amide in accordance with the equation

is followed by decomposition of a part of the excess of hydrazine with formation of ammonia, nitrogen, and hydrogen. This may be attributable

to a secondary reaction between sodium hydrazide and hydrazine or to a catalytic decomposition such as that suggested by Tanatar.¹

Action of Anhydrous Hydrazine on Metallic Sodium.—The action of anhydrous hydrazine on metallic sodium was studied in a preliminary way in a form of apparatus similar to that described by Browne and Houlehan² and used by them in studying the action of ammonium trinitride in liquid ammonia on certain metals. Small amounts of anhydrous hydrazine and sodium were brought together in approximately equivalent amounts. The hydrazine was weighed out in a Lunge-Rey weighing pipet and was introduced into the U-tube, which was immediately placed in a freezing mixture to freeze the hydrazine and prevent loss by fuming. The proper amount of sodium was then introduced into the pocket. The stopcocks were securely set in position and the U-tube was connected in the usual way with the Schiff nitrometer, filled with dilute sulfuric acid. A current of dry ammonia was now passed through the apparatus until the air was completely displaced, as indicated by the absence of bubbles of unabsorbable gas from the nitrometer. The freezing mixture was now removed and when the hydrazine had melted the sodium was brought into contact with it by jarring the apparatus slightly. The surface of the metal immediately became bright blue and soon after green in color. Gas was evolved and a yellow solid began to form and within a few minutes the whole mass assumed a light yellow color. A moment later and with scarcely any preliminary warning the material in one of the U-tubes exploded, completely wrecking the apparatus. Shortly afterward the other apparatus was destroyed by a similar explosion. Not enough gas was obtained in either case to warrant analysis with the apparatus at hand.

The experiment was repeated in a modified manner so as to eliminate the possibility of an explosion. The same kind of apparatus was employed, but a large excess of hydrazine was used and, as soon as there was evidence of the formation of the yellow solid, ammonia was condensed on the reacting mass by means of solid carbon dioxide and alcohol. The mass then became blue, owing to the solution of sodium in ammonia. The freezing mixture was removed and, as soon as the tube warmed up and the ammonia evaporated, the mass became white and shortly afterward regained the yellow color. Ammonia was again condensed on the mass and again allowed to evaporate. This operation was repeated three times, and the reacting mixture was allowed to stand for about three weeks. At the end of this time the current of ammonia was again turned on in order to carry over any gas that might have collected in the U-tube. The gas was no sooner turned on, however, than the U-tube was completely

¹ *Z. physik. Chem.*, 40, 475-80 (1902); 41, 37-42 (1902); see also Purgotti and Zanichelli, *Gazz. chim. ital.*, 34, 1, 57-87 (1904).

² *THIS JOURNAL*, 33, 1742-52 (1911).

demolished by a terrific explosion. Analysis of the gas collected in the nitrometer gave 0.2 cc. of hydrogen and 19.3 cc. of nitrogen. Further experiments carried out under somewhat different conditions confirmed the observation that both hydrogen and nitrogen, the former in relatively small amounts, were liberated during the reaction between sodium and hydrazine in the presence of ammonia. It is probable that interaction between the sodium and hydrazine first takes place with formation of sodium hydrazide and liberation of nascent hydrogen in accordance with the equation

That hydrogen is not evolved as gas, except in relatively small amounts, is probably to be explained by the reducing action on hydrazine. The presence of a large proportion of nitrogen in the evolved gases may be attributed either to the liberation of this gas as the result of some secondary reaction that occurs during the reduction of hydrazine, or to the catalytic decomposition of hydrazine; in the author's opinion, however, it is probably due to the ammonolysis of sodium hydrazide with formation of sodium amide, ammonia, and nitrogen. This reaction would be analogous to the hydrolysis of sodium peroxide with formation of sodium hydroxide and oxygen.

The extremely explosive character of the products obtained by the interaction of hydrazine with sodium amide and sodium was found to preclude the possibility of obtaining exact analytical data concerning their composition, without the use of unusual methods. Some evidence has been obtained of the existence not only of the primary sodium hydrazide, NaN_2H_3 , but also of the secondary sodium hydrazide, $\text{Na}_2\text{N}_2\text{H}_2$. Until further work has been done, however, no more definite statement can be made concerning these substances.

Apparatus Employed in the Electrolysis.

Because of the corrosive action of hydrazine upon rubber or cork it was necessary to construct the apparatus used in the electrolysis entirely of glass. Since the oxygen of the air acts on hydrazine it was also necessary that provision should be made to carry on the electrolysis in an atmosphere of some inert gas and yet prevent this gas from contaminating the resulting gaseous products. The apparatus employed is shown in Fig. 1. It consisted of cell A containing the inner tubes B and B' reaching nearly to the bottoms of the two arms. In these inner tubes the two platinum electrodes C and C' were suspended by platinum wires as shown in the figure. The inner tubes B and B' communicated, by means of capillary tubes and the two-way stopcocks D and D' either with the air or through the four-way stopcocks F and F', with the Hempel burets E and E' filled with mercury. Each arm of the cell A could be connected, through the

two-way stopcocks G and G', either with a suction pump or with a source of pure dry nitrogen. The capillary stopcocks H and H', respectively, permitted the introduction of the electrolyte from the graduated glass-stoppered mixing tube K, and the drawing off of samples at the con-

Fig. 1.

clusion of the experiment. The whole apparatus was supported by suitable clamps and, with the exception of the two leveling tubes, was rigidly mounted upon a wooden base. The stopcocks, lubricated with a small amount of anhydrous hydrazine, were securely wired in place.

General Procedure.

The cell was thoroughly cleaned and dried, and the air was displaced by dry nitrogen. The proper amount of anhydrous hydrazine was then

introduced into K and a slow stream of nitrogen allowed to bubble through it by opening either G or G' and properly adjusting H. The nitrogen was allowed to escape from K around the glass stopper, which was kept from fitting tightly by means of a fine platinum wire. In the experiments in which sodium amide was used a weighed amount of this substance was introduced directly into the hydrazine. When metallic sodium was employed, ordinary glass tubing was drawn out to small diameter and cut into approximately 10 mm. lengths. These were weighed, molten sodium was drawn up into them, and they were again weighed. A tube was then placed on a flat surface, crushed by means of a pestle and the resulting sodium wire with the crushed glass adhering was then quickly introduced into the hydrazine in the mixing tube. This operation was repeated until sufficient sodium was in solution. This gave a means of employing small amounts of sodium with a clean surface while the adhering particles of glass prevented too violent a reaction. When sodium amide is used it must be introduced a little at a time, otherwise frothing will result and the stopper will be forced out, with consequent loss of hydrazine. The nitrogen which was kept bubbling through the liquid served to prevent the oxidation at the surface and also stirred the liquid, giving a homogeneous solution.

The stopcock H was now closed, the cell was partially evacuated, H was opened and the solution was slowly sucked over into A. While passing from the mixing tube into the cell the solution was filtered through glass wool, which had previously been placed in the bottom of the mixing tube. When sufficient solution had been introduced into the cell, H was closed, D and D' were opened to the air, and nitrogen was admitted at G or G' under pressure sufficient to force the solution up into B and B' until they were completely filled. D and D' were then closed, the supply of nitrogen was shut off and G and G' were opened to the air a moment to allow the pressures and the levels of the columns of liquid in the cell arms to equalize themselves. A millimeter and a copper coulometer were connected in series with the cell and a voltmeter was shunted across the cell terminals. The voltmeter was in circuit for a few seconds only at the time of each reading, so that the total amount of current passing through it was negligible in any one experiment. During an experiment the gaseous products of the electrolysis that accumulated in B and B' were from time to time drawn over into the burets by proper manipulation of the stopcocks D, D', F, and F'. The gases were analyzed by transferring them from E and E' to a water-jacketed Hempel buret containing mercury, on the surface of which were a few millimeters of water. Any hydrazine vapor or ammonia was removed by absorption in a pipet containing dilute sulfuric acid. In order to detect possible leakage of air into the apparatus, oxygen was determined by absorption in alkaline pyrogallol. Hydrogen was

determined with palladium black and the nitrogen was obtained by difference. The palladium tube was filled with nitrogen each time before use which obviated the necessity of correcting for the contraction due to the presence of oxygen.

Details of Experiments.

Experiment 1.—After electrolysis for about five hours the solution, which was colorless at the outset, became yellow in the neighborhood of the cathode. The circuit was now broken and the solutions in the two arms of the cell were thoroughly mixed, with the result that the yellow color disappeared. After three hours of further electrolysis the cathode solution again became yellow and it was allowed to remain so until the end of the experiment. A small amount of a yellowish solid seemed to be deposited on the cathode. During the electrolysis, the total duration of which was eleven hours and thirty-five minutes, the current dropped from 9.5 to 2.9 milliamperes and the voltage rose from 89 to 107 volts.

Experiment 2.—In order to ascertain whether the yellow color that appeared in the cathode tube during the preceding experiment could be transferred to the opposite side of the cell, the solution obtained during the previous experiment was subjected to further electrolysis for a period of twelve hours with the direction of the current reversed. The yellow solution which was now in the anode tube gradually became colorless while the colorless solution in the cathode tube assumed the usual yellow color. During this experiment which was essentially a continuation of Expt. 1 the current fell from 3 to 1.2 milliamperes and the voltage increased from 90 to 102 volts.

Experiment 3.—The solution in this experiment was the same as that used in Expt. 2. It was thoroughly stirred at the outset, however, by means of the current of nitrogen. During the adjustment of the level of the mercury in the buret connected with the cathode tube, a few drops of mercury accidentally passed over through the inner tube and came into contact with the electrode, spreading over the whole surface in a peculiar manner. The electrolysis was, therefore, conducted virtually with a mercury cathode. The usual evolution of gas at the cathode did not take place. The surface of the mercury soon darkened, became purple, and was finally covered with a mass of purplish needle-like crystals which showed a brownish color at the lower end of the electrode. If this material was a sodium amalgam it gave no evidence of any chemical action even after the electrolysis had been discontinued, but stood in contact with the electrolyte apparently unchanged for several days. Gas was evolved as usual from the anode throughout the experiment which covered a period of about nine hours. The usual yellow color appeared in the neighborhood of the cathode. Toward the middle of the experiment the current dropped from 4 to 1 milliamperes and from 102 to 92 volts.

Experiment 4.—The electrolyte employed in the previous experiment was thoroughly stirred, without, however, disturbing the crystals on the cathode. The direction of the current was now reversed thus making the electrode holding the purplish crystals the anode and the clean platinum electrode the cathode. At the beginning of the experiment no gas was evolved at the anode but the crystals underwent a gradual disintegration and in a short time gave place to liquid mercury which adhered to the electrode. As soon as this transformation was complete gas was evolved at the anode while the mercury soon became tarnished to a brassy yellow color which faded out gradually when the circuit was broken and left the mercury surface bright and clean. The solution in the neighborhood of the cathode became yellow as before. The gases were not analyzed.

Experiment 5.—After the conclusion of Expt. 4 the electrolyte was thoroughly stirred until it became colorless. The mercury electrode was made the anode. As

soon as the electrolysis started the clean mercury surface became tarnished as in Expt. 4. The solution in the cathode tube became yellow. The current varied from 4.8 to 1.7 milliamperes and the voltage increased from 100 to 102 volts during the progress of the experiment.

Experiment 6.—*The contents of the cell were removed and the cell and electrodes were thoroughly cleaned and dried. The electrolyte used had, at the outset, a deep yellow color. The duration of the electrolysis was six hours and twenty-two minutes. At the end of the first half-hour the solution in the inner anode tube had become colorless. An hour later the whole solution in the anode compartment had lost its yellow color while that in the cathode compartment became deep yellow in color. The current dropped from 5.6 to 3.1 milliamperes and the voltage increased from 99 to 105 volts during the experiment.*

Experiment 7.—The electrolyte used in the preceding experiment was thoroughly stirred, with the result that it became entirely colorless. A few drops of mercury were introduced into the anode compartment so as to coat the electrode as in Expt. 3. As before, no evolution of gas was observed at the cathode during the electrolysis, but a crystalline solid similar in appearance to that previously obtained was deposited on the electrode. At the conclusion of the experiment, which lasted for ten hours and twenty-two minutes, the solution in the cathode tube had become very yellow in color. The current fell from 3.1 to 1.1 milliamperes and from 105 to 101 volts during the course of the experiment.

Experiment 8.—The mercury remaining on the electrode from the preceding experiment was removed with nitric acid, leaving the platinum clean and bright, and the cell was thoroughly cleaned and dried. The new solution employed in this case was intensely yellow and showed a much lower resistance than the electrolytes previously used. The electrolysis was continued for one hour, during which period a vigorous evolution of gas was observed at both electrodes. A blue deposit, probably consisting of either metallic sodium or an addition product of sodium with hydrazine, was at once formed on the cathode. This remained only for a short time, however, after the circuit was broken, quickly dissolving in the electrolyte with evolution of gas. Throughout the entire cell the solution remained yellow during the experiment. The current dropped from 115 to 105 milliamperes and from 85 to 80 volts.

Experiment 9.—During the preparation of the electrolyte used in this experiment a yellow solid was at first formed, which subsequently dissolved yielding a dark yellow solution. In the course of the electrolysis, which was continued for a period of one and one-half hours, a slight blue deposit was formed on the cathode. Small portions of this deposit appeared to be continuously projected from the surface of the cathode, subsequently dissolving with appreciable evolution of gas. The whole solution remained yellow, and at the end of the experiment a very slight deposit of a dull black color remained on the cathode. This deposit seemed to dissolve very slowly in the electrolyte with evolution of small amounts of gas. The current increased from 50 to 58 milliamperes while the voltage remained practically constant at 38 volts.

Experiment 10.—The electrolyte used in Expt. 9 was thoroughly stirred and was subjected to further electrolysis for a period of thirteen and one-half hours. In this case the blue deposit was not formed on the cathode but the black substance appeared as before. After the circuit was broken this material gradually disappeared with slow evolution of gas. The whole solution remained yellow throughout the experiment. The current was held practically constant at 7 milliamperes and 5.5 volts.

Experiment 11.—The solution used in the last two experiments was again electrolyzed, after it had been thoroughly stirred, for a period of fourteen hours and thirty-five minutes. The current was held practically constant at 8.5 milliamperes and 6 volts. Similar phenomena to those described under Expt. 10 were noted.

Experiment 12.—The same solution was thoroughly stirred and was electrolyzed for two hours and five minutes. Although the current density was somewhat higher than in Expt. 11 the same phenomena were noted and no blue deposit was formed. The current was nearly constant at 25 milliamperes and at 16 volts.

Experiment 13.—The conditions prevailing in Expt. 12 were duplicated as nearly as possible. The phenomena noted were similar in every particular to those described under the preceding experiments. The current averaged 24 milliamperes and 17 volts.

Further details of the experiments are summarized in Table I.

TABLE I.—RESULTS OBTAINED IN ELECTROLYTIC EXPERIMENTS.

Number of Expt.	NaNH ₂ or Na used. Grams.	N ₂ H ₄ used. Cc.	Copper on coulometer cathode.	Gas evolved at anode.		Ratio Cu : N (anode).	Gas evolved at cathode.	
				Nitrogen. Cc.	Hydrogen. Cc.		Nitrogen. Cc.	Hydrogen. Cc.

Discussion of Results.

Among the numerous ionic species that might be assumed to be present in a solution of sodium hydrazide in anhydrous hydrazine are Na⁺, N₂H₃⁻, N₂H₂⁼, N₂H⁼, and N₂⁼. That Na⁺ is present as ion is indicated by the appearance of the blue cathode deposit noted in several experiments. This indication is further confirmed by the results obtained during the electrolysis of the solutions with a mercury cathode.

The sodium liberated would, of course, act upon the solvent with formation of sodium hydrazide and evolution of hydrogen, at least part of which reacts with hydrazine to form ammonia. On the basis of this explanation it is not surprising to find that the volume of hydrogen liberated at the cathode is distinctly lower than that required for the theoretical ratio Cu : 2H. The liberation of nitrogen at the cathode may be explained as a result of the action of sodium upon hydrazine as already described in connection with the preliminary study of this reaction, that is, as a result of ammonolysis of the sodium hydrazide.

It seems reasonable to suppose that the principal anion present in the electrolyte is N₂H₃⁻. This ion in anhydrous hydrazine would be analogous to the OH⁻ ion in water and to the NH₂⁻ ion in liquid ammonia. Assuming for the present that no condensation products are formed at the anode it is probable that four N₂H₃⁻ ions would react with liberation of one molecule

of nitrogen gas and regeneration of three molecules of hydrazine, or it may be that the N_2H_3^- ions discharge upon hydrazine molecules with formation of $\text{N}_2\text{H}_2^{\equiv}$, or $\text{N}_2\text{H}^{\equiv}$ ions which then react yielding as before nitrogen gas and hydrazine. Any of these three sorts of ions might still further be considered to discharge upon hydrazine yielding the ion N_2^{\equiv} which, finally discharging on the anode, would be directly converted into nitrogen gas. In any event one atom of nitrogen would be liberated at the anode for each atom of copper deposited on the coulometer cathode.

This theoretical ratio Cu : N is approximately realized in the first eight experiments in which the concentration of the electrolyte with respect to sodium hydrazide is relatively low. The excess of nitrogen found as well as the presence of hydrogen is probably to be accounted for either by the failure of the regeneration of hydrazine to take place quantitatively or by the slight catalytic decomposition of the solvent.

In Expts. 9 to 13, inclusive, in which the concentration was distinctly higher, the ratio of copper to nitrogen was much lower, averaging 1 : 2.4. This points to more extensive decomposition either of the discharged anions or of the solvent under these conditions.

Summary.

In the present investigation it has been shown that:

(1) Sodium derivatives of hydrazine may be prepared by the action of anhydrous hydrazine upon either metallic sodium or sodium amide.

(2) Solutions of sodium hydrazide in anhydrous hydrazine readily conduct the current, yielding in general nitrogen and hydrogen at both anode and cathode. For each gram atom of copper deposited on the coulometer cathode from 1.1 to 1.5 g. atoms of nitrogen gas were liberated at the anode when the electrolyte was rather dilute. With a more highly concentrated solution, however, the ratio Cu : N varied from 1 : 2.1 to 1 : 2.6.

This investigation was undertaken at the suggestion of Professor A. W. Browne and was carried out with his coöperation.

THE SOLUBILITY OF CERTAIN DIFFICULTLY SOLUBLE SILVER SALTS.

By A. THIEL.

Received July 1, 1914.

In an article of the above title in *THIS JOURNAL*, 30, 68 (1908), which has only recently come to my attention, A. E. Hill describes several determinations of the ratio of the solubilities AgCl , AgBr , AgI and AgCNS .

He proceeds by determining the concentration of the respective anions in the solution in equilibrium with two of the salts as solid phases. Upon putting a value for silver chloride obtained in another manner into the equation, he can indirectly determine the solubility of the above-named salts on the basis of the solubility relations found according to his method. The procedure employed by Hill has repeatedly been applied for similar purposes before this and it will give reliable results in all of those cases in which the fundamental assumption is complied with, namely, that the two salts are present in the pure state as the solid phases. Apparently the author has not taken the earlier original literature upon this subject into account sufficiently and, consequently, has overlooked the fact that the necessary assumption which makes the method applicable does not apply in a number of the cases considered. Thus, F. W. Kuester and I have been able to show¹ that AgBr and AgI, as well as AgBr and AgCNS, form solid solutions, and that the solid phases in these cases, provided the concentrations of the two species of anions in the solution do not differ too greatly from one another, consist of the two saturated solid solutions. The measurements of Hill on the systems AgBr + AgI and AgBr + AgCNS do therefore in no case give the ratio of the solubilities of the pure salts, but that of the partial solubilities of these salts from the solid phase present. As one can conclude from the tables given in the case of the bromide-iodide mixture, this solid phase consisted partly of the two saturated solutions and also of an unsaturated solid phase; in the case of the bromide-thiocyanate mixture it always consisted of the two saturated solid solutions (AgBr in AgCNS and *vice versa*).

As far as the silver iodide is concerned the effect produced upon the calculated solubility is not great, since the silver bromide which is dissolved in the silver iodide does not affect the solubility of the latter in water very greatly. When fresh portions of silver bromide are added one probably obtains a false equilibrium of great inactivity, the position of which does not vary much from that of the unstable system $\text{AgBr}_{\text{pure}} + \text{AgI}_{\text{pure}}$. On the other hand, the influence of an admixture of the second component on the solubility of a solid phase is very great in the system AgBr + AgCNS, and if the results obtained by Hill nevertheless agree well with those obtained by other methods the agreement is to be considered accidental.

If the system AgCl + AgBr had been examined in the same manner, in which case an uninterrupted series of solid solutions is formed, a striking inconsistency of the solubility relations would have at once been apparent, showing the method to be inapplicable.

Among the influences responsible for the accidental agreement of the values of Hill, one might, perhaps, assume the fact that the author has

¹ *Z. anorg. Chem.*, 19, 81 (1899); 24, 1 (1900); 33, 129 (1902).

taken as the standard for the solubility of silver chloride an old result of Kohlrausch and Rose and further does not make use of the more recent values,¹ known at the time, for comparison with the other solubilities calculated by him. If this is done, conditions are not changed markedly. The evidence of solubility determinations, according to a method based upon assumptions insufficiently complied with, is not to be valued too highly in the cases under discussion. Yet one may draw the conclusion from the results obtained in the system $\text{AgBr} + \text{AgCNS}$, that the partial solubilities of the two components, as compared with the solubilities of the pure substances, are diminished in practically the same ratio. This follows from the fact that the solubilities of the two solid components in one another, in mol percentages, are of the same magnitude.

THE RELATIVE SOLUBILITY OF CERTAIN SILVER SALTS.

By ARTHUR E. HILL.

Received December 24, 1914.

The foregoing paper² by Professor Thiel contains five specific criticisms of my publication on "The Relative Solubility of the Silver Halides and Silver Sulfocyanate."³ They may be stated briefly as follows: (1) the publication criticised shows unfamiliarity with the work of Küster and Thiel,⁴ who have shown that solid solutions exist in the cases of AgBr and AgCNS and of AgBr and AgI ; (2) if equilibrium experiments had been made with the salts AgCl and AgBr , the method would have been found unsuited for solubility calculations; (3) the correct value obtained for the solubility ratio of AgBr and AgCNS is accidental; (4) the correct value obtained for the solubility ratio of AgBr and AgI is due probably to a false equilibrium, and finally, (5) all agreement shown may be due to the use in the calculations of the old value obtained by Kohlrausch and Rose for the solubility of silver chloride, instead of more recent values to which Thiel refers. Brief comment may be made on each of these criticisms.

The first criticism must be accepted as justified. I did not know of Küster and Thiel's work on these solid solutions until after the publication of my paper. In this instance it seems to me fortunate that I was unacquainted with their work at that time, for if I had read the publications I might possibly have been discouraged from using these salts in my research. In that event the equilibrium method might not have been ap-

¹ F. Kohlrausch, *Z. physik. Chem.*, **44**, 197 (1903); **50**, 355 (1908); W. Böttger, *Ibid.*, **46**, 521 (1903).

plied in a case where it has actually led to very accurate results, having to do with widely dissimilar solubilities. It should be stated, however, that during the progress of the experiments, the behavior of the precipitated silver bromide and sulfocyanate did suggest the formation of a solid solution, as was specifically noted in the publication;¹ for this reason the limitation of the experiments to certain concentrations was found necessary. It appears, therefore, that the experimental method of attacking this problem led to a correct estimate of the influence which solid solution has upon it, whereas an approach to the question from the theoretical side has led Thiel to an over-estimate of this influence.

The second criticism is founded on an assumption as to errors which might have been committed but were not. It seems to require no answer.

The third criticism is that the correct value for the silver bromide-sulfocyanate ratio is accidental. It is odd to find that the same accident, if Thiel maintains it to be such, has affected the experiments which Thiel has made on the same salts, for it is possible to calculate from Küster and Thiel's experiments² a relative solubility of these two salts in substantial agreement with my own values. One may take from Experiments 4, 5¹, 5², and 5³ of their table on page 133 the mean value 33.1 as the molecular percentage of bromide in solution in equilibrium with silver bromide and sulfocyanate, or with solid solutions of the two, if solid solution is the condition of the solid phases. The graphic representation which they give shows that this value (33.1% bromide in solution to 66.9% sulfocyanate) is very constant, even when the composition of the solid phase varies all the way from about 3% silver bromide to 97% bromide. Throughout this wide range, therefore, the equilibrium solution remains constant in composition. Applying to Küster and Thiel's experiments the same method of calculation used in my publication³ we have

$$\frac{\text{Solubility of AgBr}}{\text{Solubility of AgCNS}} = \frac{\sqrt{\text{Bromide in solution}}}{\sqrt{\text{Sulphocyanate in solution}}} = \frac{\sqrt{33.1}}{\sqrt{66.9}} = 0.703.$$

This value is in very reasonable agreement with the average value found by myself, *viz.*, 0.735. The experiment differs from my own in that the total concentration of soluble salt was about 0.1 *N*, whereas in my experiments the concentrations were 0.2 *N* and 0.05 *N*. A tabular presentation of these values will make clear the substantial agreement.

	Concentration in solution.	Solubility ratio, $\frac{\text{AgBr}}{\text{AgCNS}}$
(Hill).....	0.2 <i>N</i>	0.737
(Küster and Thiel).....	0.1 <i>N</i>	0.703
(Hill).....	0.05 <i>N</i>	0.732

³ THIS JOURNAL, 30, 68 (1908) (Equation 4).

It appears, therefore, that there is agreement within a few per cent. between Küster and Thiel's experiments, and those criticized. Since these tabulated figures represent four experiments by Küster and Thiel, equilibrium being attained from one direction, and four experiments by myself, equilibrium being attained from both directions, it seems fair, on the basis of the theory of chances, to exclude accident from the list of causes contributing to the agreement of these figures with those obtained by other methods.

It seems equally unnecessary to adopt Thiel's hypothesis of a false equilibrium as responsible for the correct results in the silver bromide-iodide solubility ratio. One can calculate again from Thiel's independent¹ experiments, substantially the same ratio found by myself. Experiments 4, 5 and 6 of Thiel's table suggest the same condition as in the case previously discussed, *i. e.*, while there is a wide variation in the composition of the precipitate, there is substantial constancy in the composition of the solution. This is evidently the solution in equilibrium with the two solids, and its composition is the mean of 0.38, 0.32 and 0.32 parts of iodide to the mean of 997, 998, and 997 of bromide, *i. e.*, 0.34 to 998. From these figures the solubility ratio is calculated as 0.01845, which is again in reasonable agreement with the mean value 0.014 found by myself. This is as close as can be expected, considering that the three figures of Thiel's taken vary by 18%, and that the analytical method used by myself was conceded to have necessarily a large possible error. The ratio of these two solubilities, as given in Thiel's compilation, has been found as follows at the temperature of these experiments (25°):

Thiel, 0.0130 by potential measurements;

Holleman, 0.0115 by conductivity measurements;

Goodwin, 0.0147 by potential measurements.

The value of Holleman, which varies most from the value 0.014 found by me, has been obtained by calculation from measurements made at other temperatures. Since the value 0.014 is between the extremes found by others, and since that value is at least partially sustained by Thiel's own experiments quoted, with a different total concentration of soluble halide present, it seems to be entirely unnecessary to explain it away by an assumption of a false equilibrium.

The final statement, that the apparent agreement may be due to the use of antiquated solubility figures, is less careful than one expects from a critic; the figures in Abegg and Cox's² compilation were used and quoted, thus taking cognizance of all reliable data existent at that time. The additional references which Professor Thiel gives are for other temperatures, and therefore entirely unsuited to the calculations under discussion.

¹ *Z. anorg. Chem.*, 24, 29 (1900).

² *Z. phys. Chem.*, 46, 11 (1903).

If any other of the accepted values for 25° is taken as standard in place of the classical value of Kohlrausch's selected by me, the agreement between my method and the others which have been used will be found to be better than was stated in my earlier publication. This is so obvious on inspection of my table¹ that it seems unnecessary to quote figures.

To Professor Thiel's conclusion with reference to the partial solubilities of silver bromide and sulfocyanate, may be added the conclusion that in these cases solid solution is not a factor of sufficient influence to affect the solubility equilibria noticeably, as proved by the experiments under discussion. The question is also suggested, though its discussion would be out of place in this reply, as to what is really meant by "solid solution" when applied to amorphous bodies such as the salts used by Thiel and myself.

ABSORPTION AND THE SURFACE TENSIONS OF AQUEOUS SOLUTION OF HOMOLOGOUS FATTY ACIDS AND ALCOHOLS.

BY MARKS NEIDLE.

Received December 23, 1914.

Duclaux² was the first to present the following relationship between the concentrations of aqueous solutions of homologous fatty alcohols and acids and their surface tensions; the ratio of the concentrations of any two homologous acids or alcohols which have the same surface tension is a constant, independent of the value of the surface tension. In symbols this may be expressed by the following equation, which will be referred to as the Duclaux equation:

$$c = bf(\gamma), \quad (1)$$

where c is the concentration, $f(\gamma)$ a fixed function of the surface tension for all members of a series, and b a constant depending upon the particular member of the series. The experimental basis for this rule comprised the surface tensions of methyl, ethyl, isopropyl, isoamyl and caprylic alcohols, and formic, acetic and butyric acids, determined by a very crude drop method. The values of the concentration ratios reproduced in Table I show as good agreement as could be expected from such rough data. The concentrations c are expressed in percentages by volume, and the temperature of observations is 15° .

Using the Morgan drop-weight method, Morgan and Neidle³ found the surface tensions of aqueous solutions of methyl, ethyl and amyl alcohols,

The concentration ratios for methyl and ethyl alcohols at concentrations which give surface tensions less than 54 dynes/cm. (Et.OH 4.53, Me.OH 9.50 g./100 cc.) agree within less than 1%. The agreement in the pair ethyl and amyl alcohols is even closer and extends to more concentrated solutions, which is also true for the pair, formic and acetic acids. Since the concentrations having the same surface tensions were found by graphic interpolation, and it is difficult to read low values with a high degree of precision, the ratios between 65 and 71.03 dynes/cm., the surface tension of pure water, were not investigated; but it is evident from the graphs that these would show even greater constancy than those at lower surface tensions. The Duclaux equation is thus established for the three alcohols

and two acids considered above, and it is very probable that it will also be substantiated for the others investigated by Duclaux, when their surface tensions are determined by the Morgan drop-weight method or any other reliable method.

Having found the surface tensions of aqueous solutions of one member of the series for a number of concentrations, the Duclaux equation may be applied to calculate those of aqueous solutions of another homolog within certain limits of concentration. For this purpose we need only determine the surface tension at any one concentration within the same limits. It will be necessary, however, before making this application to new homologs, to extend the experimental basis in order to see how far down the series the relationship holds. Such work is contemplated in this laboratory.

A relationship will now be deduced, connecting adsorption and surface tensions of aqueous solutions of homologous fatty acids and alcohols, which may be considered the physico-chemical interpretation of the Duclaux equation. The adsorption or excess concentration of the solute in the surface of a solution, expressed in mols per square centimeter, is given by the Gibbs adsorption equation

$$\Gamma = - \frac{C}{iRT} \frac{d\gamma}{dc}, \quad (2)$$

where c , the concentration of the solution, may evidently be expressed in grams or mols per 100 cc. or liter, and i is the van't Hoff factor.

From Equation 1 we have

$$\frac{dc}{d\gamma} = bf'(\gamma) \quad \text{and} \quad c \frac{d\gamma}{dc} = \frac{f(\gamma)}{f'(\gamma)}.$$

Substituting in (2), we find

$$\Gamma = - \frac{f(\gamma)}{iRTf'(\gamma)}. \quad (3)$$

But for homologs $f(\gamma)$ and $f'(\gamma)$ are the same, therefore the adsorption of their solutions having the same surface tension and the same temperature is inversely proportional to their van't Hoff factors, *i. e.*,

$$(\Gamma_1/\Gamma_2)_{\gamma,T} = i_2/i_1.$$

In the case of non-electrolytes, this relation becomes simpler, since $i_1 = i_2 = 1$, and consequently

$$(\Gamma_1)_{\gamma,T} = (\Gamma_2)_{\gamma,T}.$$

Hence in dilute aqueous solutions of the fatty acids the adsorption at a given temperature and surface tension is inversely proportional to the van't Hoff factor, but it is the same for homologous fatty alcohols.

A REVISION OF THE ATOMIC WEIGHT OF PRASEODYMIUM. THE ANALYSIS OF PRASEODYMIUM CHLORIDE.

By GREGORY PAUL BAXTER AND OLUS JESSE STEWART.

Received January 23, 1915.

CONTENTS.

Introduction. The Purification of the Praseodymium Material. The Purity of the Praseodymium Material. The Absorption Spectrum of Solutions of Praseodymium Salts. The Preparation of Praseodymium Chloride. The Purification of Silver and Reagents. The Drying of Praseodymium Chloride. The Method of Analysis. Results and Discussion.

Introduction.

Not many years ago the atomic weight of neodymium was investigated in this laboratory by the analysis of the anhydrous chloride.¹ Since considerable success was met both in preparing pure material and with the analytical method employed, the twin element praseodymium was investigated in a similar fashion; for, from the results of the earlier investigations upon praseodymium, it can readily be seen that the value of its atomic weight is far from certain.

After Auer von Welsbach² first separated the old didymium, he determined the atomic weights of the constituents by Bunsen's method of converting oxide to sulfate. Apparently the results were interchanged in publication, as Brauner has suggested, for the lower value 140.8 was assigned to neodymium.

Next Brauner,³ in 1898, starting with material purified by Shapleigh by crystallization of the double ammonium nitrate, continued the process of crystallizing this salt until neodymium was completely eliminated, then removed a trace of lanthanum by fusion with potassium nitrate, extraction of the praseodymium oxide with ammonium nitrate, and fractionation with ammonia and oxalic acid. By both the analysis of the oxalate and synthesis of the sulfate thirteen results were obtained between 140.84 and 141.19, with an average of 140.95.

Jones,⁴ in the same year, further purified double ammonium nitrate furnished by the Welsbach Light Company by crystallization until the neodymium content was about 0.06%, as determined by comparison with neodymium solutions of known concentration. Cerium was removed by the basic nitrate process, and traces of lanthanum by further crystallization of the double ammonium nitrate. Spectroscopically only a trace of lanthanum and no cerium could be detected. The oxalate was converted

³ *Proc. Chem. Soc.*, 1898, 70.

⁴ *Am. Chem. J.*, 20, 345 (1898).

to trioxide by ignition in air and then in hydrogen, and after being weighed the oxide was converted to sulfate. Twelve determinations between 140.38 and 140.54 gave an average of 140.46.

Schéele¹ also purified material first by crystallization of the double ammonium nitrate, next by extracting the black oxide with ammonium nitrate, and then by precipitation of the oxalate. In a final series of determinations oxalate was converted to trioxide in a current of hydrogen, and the oxide in turn to sulfate. From the ratio of trioxide to sulfate five values between 140.48 and 140.61 resulted.

In 1901, Brauner² confirmed his earlier work by four different methods, using similarly purified material. By igniting weighed quantities of octahydrated sulfate to the black oxide and correcting for the oxidizing power of the oxide as determined iodimetrically, he obtained from the ratio $\text{Pr}_2\text{O}_3 : \text{Pr}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ two results, 141.13 and 141.04. Weighed amounts of carefully dehydrated sulfate were then converted to oxide in the same way, yielding the values 140.96 and 140.94. Air-dried oxalate was weighed and ignited, and the oxidizing power of the oxide was determined. Other weighed portions of oxalate were oxidized with permanganate. The ratio $\text{Pr}_2\text{O}_3 : 3\text{C}_2\text{O}_3$ gave the average result 140.98. Finally, weighed amounts of oxalate, the praseodymium content of which had been found as above, were ignited to black oxide and this in turn to trioxide in hydrogen. The trioxide was changed to sulfate by solution in nitric acid and evaporation with sulfuric acid. Excess of acid retained by the salt was found by titration. In eight experiments the ratio $\text{Pr}_2\text{O}_3 : \text{Pr}_2(\text{SO}_4)_3$ yielded an average value 140.96. The mean of the four methods is 140.97, which is essentially identical with the result of Brauner's earlier work.

Auer von Welsbach³ next published the results of three determinations by the Bunsen method, without details, 140.64, 140.50, 140.56, average 140.57.

Finally, Feit and Przibylla⁴ purified praseodymium material from neodymium by crystallization of the double magnesium nitrate, and from lanthanum by crystallization of the nitrate from nitric acid solution. The higher oxide, prepared by ignition of the oxalate, was dissolved in standard sulfuric acid and the oxygen evolved was measured, as well as the excess of sulfuric acid. The oxygen evolved was subtracted from the weight of the black oxide before computing the atomic weight from the relation of trioxide to sulfuric acid used. The average result of three experiments is 140.54.

Thus it can be seen that while the investigations of Jones, Schéele,

¹ *Zeit. anorg. Chem.*, 17, 310 (1898).

² *Proc. Chem. Soc.*, 1901, 63; Abegg, *Handb. d. anorg. Chem.*, 3, [1] 263 (1906).

³ *Sitzungsab. Akad. Wiss. Wien*, 112, 1037 (1903).

⁴ *Zeit. anorg. Chem.*, 50, 258 (1906).

von Welsbach, and Feit and Przibylla indicate a value for the atomic weight of praseodymium between 140.5 and 140.6, that of Brauner, which was carried out with equal or greater care, and with material of undoubted purity, points to a value at least as high as 140.9. The International Committee upon Atomic Weights has chosen the lower figure, and recommends the value 140.6.

The various difficulties likely to be met in carrying out the methods used in the earlier determinations have been many times discussed, and a résumé of the situation is given in the paper by Baxter and Chapin on the atomic weight of neodymium.¹ It is worth pointing out that in addition to the dangers there mentioned, methods involving the use of praseodymium oxide are subject to error from the tendency of this substance to form a higher oxide of somewhat uncertain composition. While ignition in hydrogen causes reduction to the trioxide, yet it is not easy to make certain that no higher oxide is retained in the lower one. On the other hand, the analysis of the anhydrous chloride served so satisfactorily with neodymium that it seemed worth while to apply the same method to praseodymium. The results amply justified our expectations.

The Purification of the Praseodymium Material.

Through the great kindness of Dr. H. S. Miner, of the Welsbach Light Co., Gloucester City, N. J., we were fortunate enough to secure as a starting point about 10 kg. of praseodymium ammonium nitrate containing about 50% of the corresponding lanthanum and cerium salts as well as a small proportion of neodymium. Since one of the most rapid and effective methods of freeing praseodymium from the closely related elements, lanthanum, cerium, neodymium, and samarium, is the fractional crystallization of the above salt, this method of purification was chosen. According to Auer von Welsbach,² the bases separate in the order, lanthanum, cerium, praseodymium, neodymium, samarium, terbium and yttrium earths. The salt was crystallized in the usual way, that is, a concentrated, hot solution containing a small amount of nitric acid was allowed to cool and deposit the excess of salt, a period of 24 hours being allowed to secure equilibrium between the crystals and liquid. The separation of crystals and liquid was not completed by centrifugal drainage, because the labor and time involved in this operation are not repaid by any considerable increased speed of purification. The details of the crystallization are shown in the diagrams. In any given series of crystallizations a lower number always indicates a less soluble fraction. A line not connecting an end fraction with any fraction in a subsequent series indicates rejection. This crystallization was begun by Mr. W. H. Whitcomb,

¹ *Loc. cit.*

² *Sitzungsb. Akad. Wiss. Wien*, 112, 1043 (1903).

continued by Mr. B. W. Grimes and Mr. C. C. Wallace and completed by Mr. Stewart.

In the early part of the crystallization it became obvious that the original material consisted largely of the lanthanum salt, the least soluble fraction quickly becoming essentially colorless. At the same time the neodymium absorption bands, which were readily visible in the original material, rapidly strengthened in the extreme mother liquor. When this mother liquor was reduced to a volume of about 20 cc., fraction 63, its absorption spectrum was examined visually in a Hilger wave-length spectroscope. The only absorption bands which could be detected were those of praseodymium and neodymium. No sign of any of the samarium bands could be seen. Photography of the ultraviolet absorption spectrum with a Féry quartz spectrograph also failed to indicate even a trace of samarium, for the band λ 401 was absolutely lacking. The crystallization proceeded with the occasional rejection of fairly large fractions, chiefly lanthanum and cerium, at the less soluble end of each series, and the rejection of much smaller fractions, partly neodymium, at the more soluble end, until 174 series of crystallizations had been made. From the diagrams it can be seen that the number of fractions rapidly increased from the outset to a fairly constant number between 20 and 25. In series 174 a spectroscopic examination of the more soluble fractions showed that fraction 3478 contained a very small quantity of neodymium, the absorption band at 520 being faintly visible. The proportion of neodymium in this fraction we estimate to be at least as small as 0.05%. In fraction 3476 the same neodymium band could scarcely be detected. At this point fraction 3474 was removed for analysis, since it seemed likely that this fraction was as pure as any in the series 174. The fractions 3475-3480 were rejected. Fractional crystallization was then continued in a similar way with the remaining fractions, except that while the extreme crystal fractions were occasionally rejected to remove cerium and lanthanum no fractions were rejected from the more soluble end. When the extreme fraction at this end became very small, it was set aside to be added to a subsequent similar one, and the fractionation then continued. After 41 more series of crystallizations the process was discontinued because very careful spectroscopic examination of the extreme mother liquor, fraction 4383, in saturated solution with a 10 cm. layer showed no sign of the neodymium absorption band λ 520. The quantitative examination of selected fractions was then undertaken. Those chosen were 3474, 4383, 4381, 4379, 4377, 4374, 4371 and 4368. Since the less soluble fractions beyond 4368 were believed to contain cerium, they were rejected. In fact, an analysis of fraction 4368 showed it to contain about 0.4% of this element, a proportion, however, which is hardly perceptible in the atomic weight.

The Purity of the Fractions of Praseodymium Material.

The purity of the fractions in the final series was determined as follows: In neither fraction 3474 nor the more soluble fractions of the last series, 4383 and 4381, could any of the neodymium absorption lines be detected, either visually with a Hilger wave-length spectroscop or by photography with a Hilger quartz spectrograph of the Féry type. With the latter instrument photographs were made with various depths of solution and with widely varying exposures, but the results were less satisfactory than the visual ones. In order to find out what proportion of neodymium could be detected in praseodymium material, measured portions of a standard solution of neodymium ammonium nitrate were added to weighed portions of the double ammonium nitrate of fraction 4367 which was as free from neodymium as any. By using concentrated solutions and a 10 cm. layer it was found that 0.05% of neodymium could be visually detected with ease through the absorption band λ 520, and it was evident that the sensitiveness of the method could have been increased still further if necessary. Since even 0.05% of neodymium would raise the atomic weight of praseodymium by only 0.002 unit, it is obvious that the purity of the material so far as neodymium is concerned is amply sufficient.

Attempts were made also to detect neodymium by means of the spark spectrum between copper electrodes with the quartz spectrograph, but the absence of strong neodymium emission lines at points in the praseodymium spectrum which are comparatively free from lines prevents this method from being at all satisfactory.

At the other end of the series the detection of cerium was undertaken. Since lanthanum ammonium nitrate is even less soluble than the corresponding cerium salt, the absence of cerium in the praseodymium material is sufficient proof of the absence of lanthanum also. In the spark spectrum of cerium, fortunately there is a strong line of wave length 306 located at a point in the praseodymium spectrum which is comparatively free from lines. By photographing the spectrum of the spark, between copper electrodes, of praseodymium material originally free from cerium (fraction 4380) but diluted with known percentages of cerium, it was found that the limit of detection of cerium in this way lay between 0.5 and 1.0%. Assuming the atomic weights of cerium and praseodymium to be 140.3 and 140.9, respectively, one per cent. of cerium, if in the trivalent condition, would lower the atomic weight of praseodymium by 0.006 unit. Such a difference is difficult to detect by the method which we are using for the determination of the atomic weight of praseodymium. Upon photographing the spark spectra of the extreme fractions 4361, 4364 and 4368 (the most impure analyzed), it was found by comparison that the first fraction of the three was rich in cerium, the second contained much less, and fraction 4368 contained no more at any rate than 1%

Because of the uncertainty in estimating proportions of impurity from the intensity of the spectrum lines, fractions 4365, 4368, and 4371 were further tested for cerium as follows: The solution was precipitated with an excess of sodium hydroxide and the precipitated hydroxides were washed several times. Carefully scrubbed chlorine gas was next passed into the solution in order to dissolve the praseodymium hydroxide. The residual ceric hydroxide was dissolved and the process was repeated. The second residue was collected upon a filter paper, washed and ignited. Then the dissolved praseodymium was precipitated as oxalate and ignited to oxide which was weighed. In this way fraction 4365 was found to contain 2.5%, fraction 4368, 0.4% and fraction 4371, 0.1% of cerium. Besides the small and unimportant percentage of cerium in fractions 4368 and 4371, which were analyzed, the rapid falling off of the cerium percentage is worth noting.

The Absorption Spectrum of Praseodymium Chloride.

The absorption spectrum of praseodymium chloride prepared from fraction 4181 was measured in the region of the visible spectrum by means of a Hilger wave-length spectroscop, provided with an extra dense prism and achromatic lenses. The accuracy of measurement with this spectroscop was not far from $0.1 \mu\mu$ even for the longer wave lengths. Of the four broad absorption bands shown by concentrated solutions, only the one in the yellow visibly resolves into two narrower ones as the dilution increases. The wave lengths of the middle of each band at the lowest concentration at which it could be plainly seen are given below, together with observations by some other observers.¹ Praseodymium nitrate was found to give an exactly similar absorption spectrum.

Photographs of the absorption spectrum also were taken with a Féry quartz spectrograph. When the source of illumination was a Nernst filament, no absorption bands beyond the visible region could be found with any exposure or any concentration of solution. When the spark from "Nichrome" wire was employed, however, it was found that the light is completely cut off at from λ 280 to λ 270 according to the concentration of the solution, and that the solution is opaque up to the extreme limit of the spectrograms, about λ 210. In these spectrograms there were noticeable at certain concentrations very faint minima of absorption in the middle of all three bands in the blue. These minima

¹ Kayser, *Handb. d. Spectr.*, 3, 440.

could be seen over a considerable range of concentration in all three cases but the particular concentration at which they were most marked was different for the three bands. Measurements were made of the position of these minima with a comparator and the cadmium spark spectrum as a standard, and the minima were found to coincide with the centers of the absorption bands observed with the most dilute solutions both visually and in the spectrograms.

The ultraviolet absorption bands at 354 and 353 reported by Forsling¹ and the one at 346 given by Exner² correspond to strong absorption bands of neodymium. As we could not find the least trace of these bands in the spectrograms, it seems probable that they were produced by neodymium impurity.

The Preparation of Praseodymium Chloride.

Each fraction of double nitrate investigated was converted to chloride as follows: The salt was dissolved, and the solution, after dilution to about two liters, was filtered. A considerable quantity of nitric acid was added, the solution was heated to boiling and praseodymium oxalate was precipitated by an excess of oxalic acid. After the precipitate had been thoroughly washed by decantation, it was collected upon a disk of filter paper in a large porcelain Gooch crucible, and dried in an electric oven at 105°. In order to change the oxalate to oxide it was heated to dull redness in a platinum boat in an electrically heated porcelain muffle. Care was taken that the temperature should not be high enough to vaporize platinum from the boat into the oxide.³ The black oxide was next dissolved in a quartz dish in a large excess of nitric acid which had been distilled through a quartz condenser, and the oxalate was reprecipitated from dilute solution by adding a solution of twice recrystallized ammonium oxalate. After thorough washing, the oxalate was collected, dried and ignited as before. The chloride was now prepared by dissolving the oxide in a quartz dish in hydrochloric acid which had been distilled through quartz. Free chlorine was expelled by heating on an electric stove, and the salt was crystallized three or four times from concentrated solution by "salting out" at 0° with hydrochloric acid gas made by boiling the fuming solution and conducting the gas to the solution through a quartz tube. The crystals were each time centrifugally drained and rinsed in platinum Gooch crucibles.⁴ The product was preserved in quartz in a vacuum desiccator over fused potassium hydroxide.

The Purification of Silver and Reagents.

The greater part of the silver used in this work was prepared by Mr. W. H. Whitcomb for an investigation upon the atomic weight of neo-

¹ Kayser, *Loc. cit.*

⁴ Baxter, *THIS JOURNAL*, 30, 286 (1908).

dymium, which will be published shortly. No innovations were made in the processes of purification which have been frequently described in papers from the Harvard Laboratory. These processes were in brief as follows: Crude silver was dissolved in nitric acid, and the chloride was precipitated with a large excess of hydrochloric acid. The precipitate, after being washed, was dissolved in ammonia and reprecipitated with nitric acid. Then the silver chloride was reduced with sodium hydroxide and sugar, and the metal was fused on charcoal before a blast lamp. The metallic buttons were cleansed by scouring and etching, dissolved in distilled nitric acid, and the metal reprecipitated with ammonium formate made from distilled ammonia and formic acid. After thorough washing the product was again fused on the purest lime before a blast lamp. Electrolytic deposition, with silver nitrate as the electrolyte and with a dissolving anode of the pure silver buttons, followed and the electrolytic crystals were fused in a current of electrolytic hydrogen on a pure lime boat. Adhering lime was removed by etching with nitric acid, and the buttons were washed with water and ammonia, dried, and heated to about 500° in a vacuum. The silver was preserved over potassium hydroxide in a desiccator. In some of the later analyses the silver used had been purified exactly as described above by Mr. F. L. Grover for work upon the atomic weight of lead, or by Dr. H. C. Chapin for the investigation upon neodymium.

In Analyses 1 and 2 silver nitrate was employed which had been freed from chloride by repeated crystallization. This material was prepared by Dr. Grinnell Jones for work on the atomic weight of phosphorus.¹

In the preparation of reagents the precautions usual in exact work were taken. The ordinary distilled water of the laboratory was twice redistilled, once from alkaline permanganate and once alone, through block-tin condensers. Hydrochloric and nitric acids were distilled through quartz condensers, in the case of the hydrochloric acid the first and last running being rejected, in the case of the nitric acid two distillations being carried out, the first third being rejected in each distillation. Nitric acid distilled in this way does not contain more than the merest trace of chlorine, if the original acid is nearly free from the latter element.

Quartz or platinum utensils were employed wherever glass would have introduced objectionable impurities, and electrical heaters were used whenever the products of combustion of illuminating gas were to be avoided. In the crystallization of solids centrifugal drainage was always used to assist in the mechanical removal of mother liquor from crystals, except in the fractional crystallization of the praseodymium material where it would have been of little assistance.

The Drying of Praseodymium Chloride.

The drying of the chloride for analysis was effected according to the recommendations of Matignon¹ and in very much the same way that neodymium chloride was dried by Baxter and Chapin, except that while the neodymium salt was not fused, and hence retained a trace of water, which was subsequently determined, the praseodymium chloride was rendered anhydrous by fusion. Bearing in mind the earlier experience with neodymium chloride, that the dehydration of the salt must be made as complete as possible before the actual fusion occurs, in order to prevent the formation of basic salt, the salt was caused to lose its crystal water by a process of efflorescence in a current of dry nitrogen and hydrochloric acid gases at gradually increasing temperatures. Richards² has pointed out that a hydrated salt may be freed from moisture much more effectively in this way than when melting is allowed to take place. We found the transition temperature of the heptahydrate³ to be 111° but when the salt is heated in a current of hydrochloric acid gas, the melting point is somewhat lowered. Therefore, until a very considerable proportion of the water had been expelled, the temperature was kept below 100° . The temperature was then raised to about 165° where the last molecule of crystal water begins to evaporate, according to Matignon,⁴ and when the salt was essentially anhydrous it was gradually heated to about 350° . During the latter part of the heating only hydrochloric acid was passed through the tube. The aluminum block oven⁵ which had been used for heating the salt up to this point was now replaced by a sleeve which could be heated electrically and the salt was first heated to dull redness for a few minutes and then quickly to its fusing point, which Matignon⁶ states to be 818° .

The platinum boat with the salt was placed in a quartz tube which formed part of the "bottling apparatus"⁷ containing the weighing bottle with its stopper in which the boat originally had been weighed, and the bottling apparatus was connected with systems for the production of pure dry hydrochloric acid, nitrogen, and air. The hydrochloric acid gas was generated by adding c. p. concentrated sulfuric acid to c. p. fuming hydrochloric acid, and the gas was dried by passing through five towers filled with beads moistened with concentrated sulfuric acid which had previously been heated nearly to its boiling point. Nitrogen was prepared by Wanklyn's method of saturating air with ammonia and passing the mixture over

hot copper gauze. The excess of ammonia was removed by dilute sulfuric acid, and the nitrogen was further purified and dried in towers containing glass beads moistened with silver nitrate solution, fused potassium hydroxide, concentrated sulfuric acid, and phosphorus pentoxide. Nitrogen made in this way invariably contains a small proportion of hydrogen,¹ owing to catalytic decomposition of the excess of ammonia on the copper tube, but this gas would do no harm in the present instance. Air was purified and dried by reagents similar to those used for purifying the nitrogen. The apparatus was constructed wholly of glass with either ground or fused joints, except at the beginning of the air and nitrogen apparatus. By means of stopcocks any one of the three gases could be delivered to the bottling apparatus at will. This apparatus is identical with that used by Baxter and Hartmann² for the drying of cadmium chloride, and by Baxter and Grover³ for the drying of lead chloride. After the fusion of the neodymium chloride, the hydrochloric acid was displaced by nitrogen and the nitrogen in turn by air. Then the boat and contents were transferred to the weighing bottle, which was allowed to stand in a desiccator near the balance for some hours before being weighed.

A solution of praseodymium chloride, which has been fused in this way, sometimes contains a small amount of insoluble glistening particles, practically invisible unless examined in a strong light in a vessel whose curvature magnifies their apparent size. A similar difficulty was met by Baxter and Chapin in the preparation of pure anhydrous neodymium chloride. Under unfavorable conditions, which will be described shortly, the amount of this insoluble material may be considerably augmented, but when prepared under the most favorable conditions the salt dissolves rapidly without leaving even a trace of insoluble matter. Even when a small amount of insoluble material is formed, a clear solution is usually obtained after a day or two. The conditions under which the extent of the difficulty is too small to have an appreciable effect upon the results, have been found to be very careful preliminary dehydration of the salt, and a very short period of fusion. These conditions were maintained in the preparation of all of the specimens of material which were analyzed, but only in Analyses 5, 6, 9, 10, 16, 24, 25, 30, 31, 38 and 39 was the solution of the salt absolutely clear at the start.

Many experiments were carried out, however, first, to find out the nature of the insoluble matter, and second, to discover the extent of the difficulty. At the outset there seemed to be three possibilities as to the nature of the substance. The most probable one was that the substance is a basic

¹ Dr. R. C. Wells first pointed out this fact to us.

² THIS JOURNAL, 37, 113 (1915).

³ Investigation not yet published.

chloride, but it was possible that it might be either an insoluble allotropic form of the trichloride or a lower chloride, *i. e.*, praseodymium dichloride. The fact that prolonged fusion of the salt invariably resulted in the formation of relatively large amounts of insoluble material seemed to point toward one of the last two explanations, although there seems to be no certain evidence of the existence of such compounds in the case either of praseodymium or of other rare earths.

In order to find out the composition of the insoluble substance, amounts large enough to be analyzed were prepared by dehydrating the crystals with the usual care, and then fusing the salt for periods from one-half hour to one hour in a current of dry hydrochloric acid gas. The product was then treated with water, and as soon as the soluble portion of the salt had dissolved, the insoluble residue was collected upon a small weighed platinum-sponge Gooch crucible, dried and weighed. The residue, which was distinctly crystalline, did not change in appearance during the drying, so that it is improbable that its composition was appreciably altered during this treatment. The praseodymium content of the residue was then determined by dissolving the residue from the crucible in dilute hydrochloric acid, precipitating the base with ammonium oxalate, collecting the precipitate upon a filter, and igniting in a weighed platinum boat. The weight of the black oxide Pr_2O_3 was checked by igniting the residue in a stream of hydrogen and reweighing. The weights of oxide obtained in two experiments correspond very closely to the weight which should be obtained, assuming the residue to be praseodymium oxychloride, PrOCl . About 6 g. of anhydrous salt were used in each experiment.

60	0.0131	0.0117	0.0115	0.0090	0.0104	0.0114	0.0112

The composition of the residue was further checked by determining the chlorine content. Residues were collected and weighed as above, and then after solution in dilute nitric acid, the chlorine was precipitated as silver chloride, collected and weighed. During the solution of the residue the crucible and contents were placed in a closed tube through which a current of air was passed into a solution of ammonia, so that in case chlorine was liberated during the solution, it would be caught in the ammonia. The results of the chlorine determinations check closely those of the praseodymium determinations.

Since it is obvious that, if the oxychloride is formed from the trichloride, a loss in weight must occur, further experiments were carried out to discover whether during the formation of the larger amounts of insoluble residue, when the fusion is prolonged, the loss in weight of the salt corresponds to the weight of residue produced. In these experiments the hydrated salt was first very carefully dried, then quickly fused and weighed. During this treatment little, if any, insoluble material is formed. Then the boat with the salt was returned to the quartz tube, and after the apparatus had been thoroughly swept out with dry hydrochloric acid, the salt was brought to the fusing temperature, which was maintained for one hour in every case. After the salt had been reweighed, the insoluble residue was determined as previously described and a few tenths of a milligram of salt which sublimed from the boat to the quartz tube were dissolved in water, the solution was evaporated and the residue was heated and weighed. The weight of sublimed material was of course added to the weight of the fused salt before determining the loss in weight during fusion.

These experiments agree very satisfactorily with those in which the praseodymium and chlorine were actually determined, in indicating beyond question that the insoluble residue is the oxychloride.

The surprising feature of these results is that the amount of insoluble matter increases with the period of fusion instead of decreasing or even remaining constant. The obvious conclusion is that some source of oxygen exists in the fusion atmosphere. To be sure, in the first of the experiments for the determination of the insoluble residue a tiny hole was discovered in one of the fused joints of the hydrochloric acid apparatus, and in this experiment the weight of insoluble residue was found to be about ten times as large as in the subsequent experiments. Fortunately the defective joint was a comparatively new one, and could have affected only four of the fusions of the salt for analyses. The analyses involved are Nos. 12, 13, 14, 15, 34, 35, 36 and 37. The hole was excessively small, however, and it is not at all certain that any real difficulty was produced. It seemed possible that the hydrochloric acid gas might contain air, originating in the reagents used for generating the gas, or possibly from incomplete sweeping out of the purifying train. By passing the hydrochloric acid gas into water under an inverted tube after the apparatus had been thoroughly swept out, we found that it actually did contain a trace of air. We tried in some experiments to avoid the first difficulty by passing the hydrochloric acid gas through a hydrochloric acid solution of cuprous

chloride before it entered the drying towers, and in order to avoid the second difficulty the apparatus was swept out even longer than before previous to the fusion of the salt, but neither of these remedies seemed to have any effect upon the formation of the basic salt. Another source of oxygen might be moisture. However, concentrated sulfuric acid has been found by Morley¹ to be a very effective drying agent. One liter of gas passed over concentrated sulfuric acid retains only 0.003 mg. of moisture. In order to make sure that the hydrochloric acid was really as dry as this, the gas was passed for several hours through a U-tube cooled with alcohol and solid carbon dioxide. A very small amount of white solid was condensed in the tube, presumably a hydrate of hydrochloric acid. But even on the assumption that all of the moisture is removed from the gas by the salt during the fusion, it seems impossible that the residue should have formed wholly from moisture contained by the acid gas. Still another possibility was that the quartz tube was attacked by the acid gas to yield moisture and a chloride of silicon. This point was tested by drying and fusing the salt in a platinum tube instead of in a quartz tube, but even under these conditions the insoluble residue was formed. We are still somewhat uncertain as to the cause of the formation of the basic salt during prolonged fusion, although incomplete preliminary drying is invariably the cause when the fusion period is short, but we are inclined to the opinion that the difficulty is due to a trace of air in the hydrochloric acid gas.

Since we were unable to avoid the formation of the insoluble material in every case, in two experiments in which the salt was dried as for analysis and then fused for a short period, the insoluble residue was collected and weighed. The results of these experiments follow. As before, about 6 g. of anhydrous salt were used in each experiment.

Period of fusion.....	0.5 min.	4 min.
Wt. of insoluble residue.....	0.0001 g.	0.0010 g.

In order to discover whether the basic salt dissolves to an appreciable extent, in experiments with three separate portions of material which had been collected, dried and weighed upon a platinum-sponge crucible, about a liter of water was allowed to flow slowly through the crucible during the course of an hour. The crucible and contents were then dried and reweighed. The losses in weight per liter of water were 0.9, 0.5 and 0.3 mg. While these figures are undoubtedly somewhat less than the real solubility in water, they are probably far greater than the solubility in dilute praseodymium chloride solution. This explains the extreme slowness with which a mere trace of the basic salt dissolves in the solution of the neutral salt and supports the conclusion that the quantity of basic salt present in the material fused for a short time is very small.

¹ *Am. J. Sci.*, 30, 141 (1885).

In preparing the salt for the actual analyses the period of fusion was less than one minute, so that the weight of residue certainly must have been considerably less than 1 mg. But since even as large a proportion as 1 mg. of oxychloride in 5 g. of salt, if it dissolves eventually, would raise the apparent atomic weight of praseodymium by only 0.028, we feel that little danger is introduced by not attempting to apply any correction for the residue.

In a research upon the atomic weight of neodymium carried out immediately at the conclusion of this research, similar evidence was obtained as to the nature of the insoluble neodymium compound which forms under essentially the same conditions.

The Method of Analysis.

After the salt had been fused and weighed, the boat was transferred to a glass-stoppered Erlenmeyer flask and treated with about 500 cc. of pure water. In eleven of the analyses the salt dissolved immediately, leaving an absolutely clear solution. In the remainder of the analyses, after the bulk of the salt was in solution, by close inspection a small quantity of the insoluble basic chloride could be seen. On allowing the flask to stand for a considerable period, 24 to 48 hours in general, this basic salt disappeared, and in a few instances gentle heating was used to accelerate its solution. When the solution was clear, it was transferred quantitatively to the 3 or 4 liter glass-stoppered Erlenmeyer precipitating flask. The rinsings of the weighing bottle were added and the solution diluted to a volume of from 1200 to 1500 cc. In the meantime a quantity of pure silver as nearly as possible equivalent to the praseodymium chloride was dissolved in nitric acid, in a dissolving flask provided with a column of bulbs to prevent loss by spattering while the metal was dissolving. After diluting the solution of silver nitrate, it was heated to eliminate nitrous acid, and then further diluted to about the same volume as the praseodymium chloride solution. The silver nitrate solution was poured into the chloride solution, both being cold, in small portions with continual gentle agitation. When the silver nitrate had been completely transferred to the precipitating flask, the flask was stoppered and gently shaken to insure thorough mixing, and allowed to stand for several days with occasional shaking. Then it was cooled with ice water in order to lower the solubility of the silver chloride, and after standing for a day in the ice bath, portions of the mother liquor were tested for excess of silver or chloride by adding to separate portions equal amounts of 0.01 N chloride and silver solutions and comparing the opalescences in a nephelometer. If a deficiency of either chloride or silver was found, this deficiency was made up by adding 0.01 N silver or chloride solution. The amount of either added, expressed in the silver equivalent, is given in the tables of results under the heading "Silver added or subtracted." When

equilibrium had been reached, 0.05 g. of dissolved silver nitrate for each liter of supernatant liquid was added to render the silver chloride less soluble. After the solution had been allowed to stand for at least a day, usually much longer, at room temperature, the precipitate was washed many times by decantation with a solution containing 0.05 g. of silver nitrate per liter, and several times with ice-cold water, and transferred with cold water to a large weighed platinum-sponge Gooch crucible. The crucible with its contents was dried for at least 12 hours in an electric air bath at 160° , cooled in a desiccator and weighed. The crucible had originally been dried in exactly the same way. In order to find out how much moisture had been retained by the dried silver chloride, the greater part of the salt was transferred to a porcelain crucible which was weighed. Then the crucible was heated to the fusing point of the silver chloride and reweighed. The loss in weight is assumed to represent residual moisture. On an average 0.004 % of moisture was found, a proportion which is in accord with earlier experience in the Harvard laboratories.

The solubility of silver chloride in the filtrate and silver nitrate wash waters, which both contained 0.05 g. of silver nitrate per liter, was computed from the solubility products as found by Kohlrausch¹ at 20° and 25° , 1×10^{-10} and 1.7×10^{-10} , respectively. At 20° the solubility in 0.0003 *N* silver nitrate solution is 0.05 mg., at 25° 0.08 mg. per liter. The former correction was used during the colder months when the laboratory was maintained at about 20° , the latter correction in four analyses which were completed in summer. The total correction in most cases fell between 0.2 and 0.3 mg. The silver chloride dissolved in the aqueous rinsings as well as that obtained by rinsing the precipitating flask with ammonia was determined by comparison with standard solutions of chloride in a nephelometer, the usual precautions being taken to secure uniformity of precipitation. As in earlier researches it was found desirable to dissolve in ammonia the cloud of silver chloride in both the standard solution and that being analyzed, and then to reprecipitate with nitric acid.

Corrections were of course applied for any chloride introduced in order to compensate for excess of silver, and also for the standard chloride solution added to the portions which were tested in the comparison, for these portions were always returned to the precipitating flask. The latter quantity amounts to 1.328 mg. for each test which was made in the comparison. Because of the comparatively large size of this correction, the standard silver and chloride solutions were made up, preserved, and measured with great care.

Weighings were carried out on a No. 10 Troemner balance, sensitive at least to 0.02 mg. In order to avoid difficulties from changes in at-

¹ *Z. physik. Chem.*, 64, 167 (1908).

atmospheric humidity and density, the receptacles containing the salts were always weighed by substitution for counterpoises as nearly as possible like the objects both in material, volume, and external surface. The balance case was provided with a small amount of radioactive material to dissipate electrical charges produced during the transference of the objects to the balance pans. The weights were standardized to hundredths of a milligram by the method described by Richards.¹ Vacuum corrections were applied as follows:

Results and Discussion.

In order to show that no considerable error occurred, owing either to occlusion by silver chloride or from loss of silver chloride in solution, the ratio between the silver used and the silver chloride obtained has been calculated in the eighteen pairs of analyses for which the data are available.

The average ratio of silver to silver chloride is within less than four thousandths of a per cent. of that obtained by Richards and Wells,¹ 0.752634 : 1.000000. Part of the discrepancy is due to the fact that in a few analyses, notably Nos. 12, 13 and 14, the platinum-sponge crucible allowed traces of solid silver chloride to pass through. The difficulty

was not detected in time to determine the extent of the error, but in one of these analyses silver chloride was found to have settled out of the mother liquor on long standing. This is undoubtedly the reason why the atomic weight of praseodymium determined in these analyses is slightly higher than in most other experiments. Needless to say, the crucible was repaired and in Analyses 15 and 16, made subsequently with the same fraction of material as Analyses 12, 13 and 14, the results are in accord with the general mean of all the determinations. These defective analyses as well as a very few other discrepant determinations, have not been omitted in computing averages, since, because of the large number of experiments, their influence is not large.

Average, 140.923

Average of all Individual Determinations, 140.924

When the results are averaged by fractions, further evidence is added to

that obtained by the spectroscope, that all the fractions analyzed were of a high degree of purity.

Fraction 4383, which contained all the neodymium which may have accumulated in forty-one series of crystallizations, gives a slightly lower instead of higher figure than the average, while fraction 4368 which contained more cerium than any other fraction gives a result identical with the average. This close similarity is very striking when one considers that a range of sixteen fractions is included in those examined. Fraction 3474, selected at an earlier stage of the fractionation as being very pure, also shows no sign of being different from the other fractions.

The foregoing results leave little opportunity for choice. There seems to be no reason for preferring the value obtained with any one or more fractions to those resulting with the others. Possibly the average of Analyses 5, 6, 9, 10, 16, 24, 25, 30, 31, 38 and 39, 140.913, is more reliable than the average of all, for in these analyses the praseodymium chloride dissolved rapidly and completely at the start, and was probably entirely free from basic salt, but we believe that the final corrected average of all the experiments, 140.92, represents fairly the best material we succeeded in preparing. This result is not far from the value obtained by Brauner in both his researches, but is over three-tenths of a unit higher than the choice of the International Committee upon Atomic Weights.

We are indebted particularly to the Carnegie Institution of Washington for pecuniary assistance in carrying out this investigation, and also to the Cyrus M. Warren Fund for Research in Harvard University for indispensable platinum vessels, as well as to Dr. H. S. Miner of the Welsbach Light Company for the praseodymium material.

CAMBRIDGE, MASS.

RECENT WORK IN INORGANIC CHEMISTRY.

By JAS. LEWIS HOWE.

Received January 25, 1915.

It might seem too soon for publication of chemical research to feel the effects of the war, especially as nearly half of the period that has elapsed since the outbreak of hostilities covered the summer vacation in the continental universities, yet that there has already been a decided influence is apparent in the fact that the *Zentralblatt* from August 9 to December 9 contains only 964 pages as against 1548 pages for the similar dates in 1913. A far more serious diminution of research is to be expected, when we realize that such a large proportion of the students of European and Colonial universities are "with the colors."

There is little that is particularly striking to chronicle in the progress of inorganic chemistry in 1914. The only radical departure from well-established ideas is found in variations in the atomic weight of lead from different sources. The theoretical considerations are discussed by Fajans¹

¹ *Physikal. Ztsch.*, 14, 951, and *Sitzber. Heidelb. Akad. Wiss., Math-naturw. Kl.*, 1914, 11, *Abh.* 22.

according to which it appears that the end product of decomposition in the uranium-radium series, Ra G, must be lead, but that it would have an atomic weight of 206.0, instead of 207.1, the atomic weight of ordinary lead. Similarly, the end products of the other radioactive series would have atomic weights varying from 206 to 210, that of the end-product of the Ra C₂ series. The first case has been studied by Richards¹ by determining the atomic weight of lead from different sources. While for ordinary lead from commercial acetate and nitrate the figure 207.15 was found, using the same methods of analysis the atomic weight of lead from English pitchblende was found to be 206.86 and from Joachimsthal pitchblende 206.57. Almost this same figure was found for Colorado carnotite, while uraninite from North Carolina gave a still lower value, 206.40. In general, the greater the radioactivity of the mineral, the lower the atomic weight of the contained lead. This variation is also confirmed by Maurice Curie² who finds the figure for lead in carnotite 206.36, in pitchblende 206.64, in yttriotantalite 206.54, but that in monazite was 207.08. From these results there would seem little doubt but that in lead there is a variable atomic weight, depending on its origin, and further work along this line will be awaited with interest.

Among the more general papers of the year is one by Kullgren³ on the hydrolysis of inorganic salts. Using the inversion method, the hydrolysis of a large series of salts, chiefly chlorides and nitrates of bivalent metals, was determined at 85.5° and 100°. In most cases the hydrolysis proceeds according to the equation: $\text{RCl}_2 + \text{HOH} = \text{R}_{\text{Cl}}^{\text{OH}} + \text{HCl}$, the value being the same for chlorides and nitrates, (except ZnCl_2). The reaction with aluminum salts appears to be with two molecules of water: $\text{AlCl}_3 + 2\text{HOH} = \text{Al}_{\text{Cl}}^{(\text{OH})_2} + 2\text{HCl}$. (Lind has found by conductivity methods the hydrolysis of trivalent ruthenium also to be two-thirds.) In these salts with moderate hydrolysis the hydrolysis-constant is seldom a real constant. The hydrolysis of HgCl_2 (1.33) and PbCl_2 (1.49) is almost independent of dilution, but in the other salts there was some increase of hydrolysis. The degree of hydrolysis is decreased by the presence of neutral salts and this action is independent of the temperature. In a study of organic compounds of tin, Pfeiffer⁴ obtained the first hydrolytic product of stannic chloride and of stannic bromide, $\text{SnCl}_3(\text{OH}) \cdot 3\text{H}_2\text{O}$ and $\text{SnBr}_3(\text{OH}) \cdot 3\text{H}_2\text{O}$, by extracting a not too dilute aqueous solution of the halide with ether and recrystallizing the product obtained from water. From his work he draws the conclusion that these hydrates, as well as $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$ and $\text{SnBr}_4 \cdot 4\text{H}_2\text{O}$, are not aquo-salts, but simply addition compounds (Anlagerungsverbindungen). The coördination number of the tin atom is 6, two of the coördination positions being occupied by water. The structure thus becomes $[\text{Cl}_4\text{Sn}(\dots\text{OH}_2)_2] + 3\text{H}_2\text{O}$, etc.

Cryoscopic measurements in nonaqueous solutions is a subject of great interest and slow development. Isbekow⁵ has worked with AlBr_3 as a

solvent, and finds that in this medium such substances as AlCl_3 , AlI_3 , CBr_4 and S, which give non-conducting solutions, have normal molecular weights. On the other hand HgBr_2 , SbBr_3 , BiBr_3 , CdBr_2 , PBr_3 and ZnBr_2 , whose solutions are electrolytes, are polymerized, the first three increasing in polymerization with the concentration. It appears as if in these cases the salt forms a complex ion with the solvent, which decomposes with increasing dilution into the simple undissociated molecule. Olivari¹ has used iodine as a solvent and worked chiefly with organic compounds, which at great dilution show normal molecular weights, but which associate with increasing concentration. The associating tendency is least with hydrocarbons and increases with the presence of hydroxyl groups. In concentrated solutions the molecule of sulfur is S_8 , but lower values are obtained on dilution. Selenium gives values between Se and Se_2 , the latter only in concentrated solutions. With tellurium, compounds are formed, as is evidenced by the evolution of heat, which seem to have simple molecules of the formula TeI_x . Iodides of the alkalis and organic iodides give abnormal results, the molecular weight increasing with concentration to a maximum value and then decreasing.

The action of ultraviolet light on metals has been investigated by Kimura.² He finds that when metals are covered with a layer of water or alcohol and exposed to ultraviolet light they are corroded and the material removed goes into solution in a colloidal form. The colloidal particles seem to consist of both metal and hydroxide. An alloy of 90% cadmium and 10% antimony showed no corrosion in vacuum but was acted on in the air, and much more strongly in pure oxygen. Kimura concludes that the action in air is due to the formation of ozone by the influence of the ultraviolet light. Under water, where the corrosion is much greater, hydrogen peroxide is in part the active agent, but not the exclusive one, as was shown by experiments on the action of hydrogen peroxide on silver.

From experiments at Kilauea in 1912, Brun concluded that in the gases of this volcano there was no water to which a magmatic origin could be attributed. More recent observations by Day and Shepherd³ indicate the reasons why Brun failed to detect this water, and show its presence. The gases were drawn by Day and Shepherd by means of a metal tube inserted in a narrow lava crack from direct contact with molten lava. Considerable quantities of water were obtained, which could only have been of magmatic origin. The gases, chiefly SO_2 and CO_2 , with a little CO, contained nitrogen, but no argon, as would have been the case had any atmospheric gases been present. The water collected was milky from precipitated sulfur, but contained neither chlorine nor titanium. These results are analogous with those of other observers on the gases of Mount Etna, except that here, as well as at Vesuvius, Stromboli and Santorin, large amounts of chlorine are present. It must be concluded that magmatic water plays a large role in volcanic eruptions, as has been generally believed.

The work of Ephraim⁴ on "Nebenvalenz," which was described last year, has been extended to the addition compounds of the halides of the

¹ *Atti accad. Lincei, Rome* [5] 22, ii, 697; 23, i, 41.

² *Mem. Coll. Sci. Engin., Kyoto*, 5, 253.

³ *Compt. rend.*, 157, 958, 1027.

⁴ *Ber.*, 46, 3742.

bivalent metals with substituted ammonias. Many of the addition compounds formed are analogous to those formed with ammonia, while others differ. The influence of the atomic volume of the central metal upon the affinity of the compound is clear, and in the case of Ni, Co, Fe, and Mn, the expression $^3\sqrt{v} \cdot ^3\sqrt{T}$ (v = atomic volume of the metal, T = dissociation temperature) is nearly a constant, as was found to be the case in the addition products with ammonia. The affinity is also strongly affected both by the anion and also by the neutral portion of the molecule, but the irregularities are so far too great for much generalization. Pfeiffer,¹ working with the stannic halides, finds tin tetrachloride to possess the greatest affinity in the formation of addition products with ethers, esters, and nitriles. The addition compounds of the tetrabromide are far less stable, and no addition compounds were formed with any of the esters tested. If one chlorine atom in the tetrachloride is replaced by the methyl group, the affinity for esters, etc., almost ceases, while the substituted bromide forms no such addition products. All three tetrahalides form addition products with alkali salts and related compounds, as do the mono- and di-alkyl halides, but this is no longer the case with the stannic halides in which three or four of the halogen atoms are replaced by alkyl groups. The same is true regarding the tendency to unite with pyridine, but with ammonia the trialkyl derivatives, $R_3\text{SnX}$, form addition compounds, though this is not the case with the tetraalkyl compounds. Pfeiffer concludes that the affinity of the "Nebenvaleanz" of tin decreases from chloride to bromide, and from bromide to iodide, and also decreases as the halogen atoms are progressively replaced by alkyl or phenyl groups. This is in general accord with the work of Ephraim.

Werner has continued his work² with rather striking results, especially in two particulars. First, in his study of the asymmetrical cobalt atom, he has prepared compounds with two cobalt atoms in the nucleus, to each of which are attached two ethylenediamine groups, and which are linked together by a NH_2 and a NO_2 group; these latter groups are held, half by primary and half by secondary valence. Such a compound ought to be capable of existing, like the analogous tartaric acid with two asymmetrical carbon atoms, in four forms, dextro and levo, racemic, and also the meso, or internally compensated inactive form. All of these forms were actually prepared by Werner in the series: $[\text{en}_2 \text{Co} \begin{smallmatrix} \text{NH}_2 \\ \text{NO}_2 \end{smallmatrix} \text{Co en}_2] \text{X}_4$. The inactive forms were resolved into the dextro and levo forms by means of the active bromocamphorsulfonates, and the mixture of these two active forms gave again the inactive racemic form, which could be again resolved into the active forms. On heating with water the active forms become inactive, passing over into the meso forms which cannot be resolved into active isomers by the bromocamphorsulfonate. The meso salts are less soluble than the corresponding racemic salts, 100 parts of water dissolving 1.95 parts of the meso-bromide and 2.31 of the racemic bromide, 2.44 of the meso-iodide and 3.75 of the racemic iodide. From the optical behavior of the salts it appears that here there can be no difference between primary and secondary valence. Further work was done by Werner on similar compounds where the two cobalt atoms in the nucleus are linked together by

¹ *Z. anorg. Chem.*, **87**, 335.

² *Ber.*, **46**, 3674; **47**, 1954, 1961, 2171, 3087.

O₂ instead of NO₂, one of the cobalt atoms being quadrivalent. Here there should be four active forms and two racemic, several of which were obtained. These compounds are characterized by an extraordinary large rotation (in the bromide $[\alpha] = \pm 840^\circ$). Much more striking is the last piece of work which has come from the Zürich laboratory, an optically active substance which contains no carbon, and which has a rotation $[\alpha]_{560} = \pm 4500^\circ$, with a most extraordinary anomalous rotation-dispersion. The value of $[\alpha]$, for example, for wave-length $643.5 = -2100^\circ$ for $617.0 = 0^\circ$, for $560 = +4446^\circ$, for $495 = 0^\circ$, and for $478 = -858^\circ$. This compound belongs to the type (Co en)₃X_n, the place of ethylenediamine being taken by

$$\begin{array}{c} \text{HO} \\ | \\ \text{Co}(\text{NH}_3)_4 \\ | \\ \text{HO} \end{array}$$

[Co($\begin{array}{c} \text{HO} \\ | \\ \text{Co}(\text{NH}_3)_4 \\ | \\ \text{HO} \end{array}$)₃]X₆, a dodekammine-hexol-tetracobalti-salt. The in-

active form has been known for some time, and is prepared from the chloro-aquo-tetrammine-cobalt chloride by the action of dilute ammonia, with fairly good yield. The resolution into the active constituents is accomplished by the bromocamphorsulfonate method. Using the strychnine method Werner has resolved the rhodium oxalates into optical isomers, and here he finds anomalous rotation-dispersion, the potassium salt of the dextro acid having values of $[\alpha]_c = -26.4^\circ$, $[\alpha]_D = 0^\circ$, and $[\alpha]_B = +114.4^\circ$. He also finds that some racemic forms of cobalt compounds can be split into the active forms by crystallization, the solution being inoculated by traces of the active form, and this in some cases at least not necessarily of the same compound.

Both Ramberg¹ and Tschugajew² have continued their work on the complex compounds of platinum with the organic thio-compounds, the former using ethyl- and ethylene-thio-glycolic acid and obtaining both *cis*- and *trans*-isomers. In working with the thiobases, Tschugajew found much difficulty in determining the composition of the complex kation, owing to the tendency to form salts of the Magnus type, platinum being thus present in both kation and anion. He has now found that these salts can be resolved by salts of several acids, as nitroprussides, chlororhodates, phosphotungstates, but, best of all, by picrates, and he recommends picric acid as a valuable reagent for complex kations. He has also prepared a number of complex platinum salts with hydrazine and with both hydrazine and ammonia. In these the hydrazine acts like the ammonia and occupies only a single coördination-position. In addition to the large number of complex salts of the metals of the platinum group which he has already described, Gutbier has now studied the bromoplatinates,³ the bromoaurates,⁴ and the chloro- and bromo-tellurates.⁵ Large numbers of salts of each of these classes have been prepared, both with inorganic and organic bases, and are fully described. In the balance of this review the order of the periodic table will be followed.

Group II.—K. A. Hofmann⁶ has found fused anhydrous magnesium chloride an excellent solvent for many inorganic oxides, and from the melt

¹ Ber., 46, 3886; 47, 730.

² Z. anorg. Chem., 86, 241; Ber., 47, 2446.

³ J. prakt. Chem., [2] 88, 409; Sitzber. physik.-med. Soz., Erlangen, 45, 25.

⁴ Z. anorg. Chem., 85, 353.

⁵ Ibid., 86, 169.

⁶ Ber., 47, 238.

fine crystals are generally obtained. The oxides may be directly dissolved, or other compounds used, especially the sulfates, which undergo decomposition in the melt. The magnesium oxide which is always present in the crystallized mass may be removed by acetic acid or dilute hydrochloric acid. By using iron filings, or dehydrated ferrous sulfate, or Fe_2O_3 , and varying the time of fusion, $\text{Mg}(\text{FeO}_2)_2$, $\text{Fe}(\text{FeO}_2)_2$, or the intermediate magnesio-ferrites, are obtained. Fine crystals of magnesium borate, $3\text{MgO} \cdot \text{B}_2\text{O}_3$, are formed in the melt of MgCl_2 with boric acid, and $3\text{MgO} \cdot \text{U}_2\text{O}_6$ when uranic oxide is used. CeO_2 can be obtained in brilliant crystals of extreme hardness, by the use of cerium sulfate. These crystals are colorless, but if small quantities of rare earth sulfates (Er, Nd, Pr) are added to the fusion beautifully colored crystals are formed. ZrO_2 may be similarly obtained. From the fusion with erbium, neodymium, praseodymium, and samarium-sulfates, the oxychlorides are gotten, ErOCl , NdOCl , PrOCl , SmOCl , and these show in reflected arc light the characteristic spectra of the metals. This method is suggested as a useful one in the investigation of these, and possibly other rare earths. Hedvall¹ has extended his study of Rinman's Green, which proved to be a solid solution of the components, to the red produced by heating magnesium oxide with cobalt compounds. The two oxides were heated directly with a potassium chloride flux, at temperatures from 1100° to 1400° . Crystals were formed which varied under the microscope from colorless to ruby-red, and which were octahedra, often with cube faces. While it was not possible to follow the homogeneity of the crystals through the whole series, for a considerable interval—38–79% CoO —they could be shown to be homogeneous, and it seems probable that a complete miscibility subsists between MgO and CoO in all proportions. The specific volume of the products decreases continuously with increasing content of CoO .

Group III.—The work of Stock on the borides of hydrogen, which was described in the review of last year, has been extended to the reactions of these borides on the alkalis² and on the halogens.³ For action with the alkalis H_{10}B_4 was chosen, since H_6B_2 is so sensitive to the presence of moisture. With both the borides, however, the same product is formed and hydrogen is evolved, molecule for molecule. The reaction is: $\text{H}_{10}\text{B}_4 + 4\text{KOH} = 4\text{KOBH}_3 + \text{H}_2$. The salt formed, potassium hypoborate, is stable in the absence of moisture, and at 0° its solution can be preserved for several hours without decomposition. At ordinary temperature the solution decomposes with evolution of hydrogen and formation of KBO_2 : $\text{KOBH}_3 + \text{H}_2\text{O} = \text{KBO}_2 + 5\text{H}$. The solution gives an alkaline reaction, owing to hydrolysis. It is a powerful reducing agent, resembling in this respect the hypophosphites, which it also resembles in structure. Solutions of aluminum, zinc, manganese, and the alkaline earths are precipitated, hydroxides and borates being formed, while in solutions of silver, bismuth, mercury, arsenic, and antimony, a dark precipitate of the free metal appears at once. In copper solutions copper hydride is formed. The most characteristic reaction is that with nickel solutions, in which black, insoluble nickel boride, Ni_2B , is precipitated; in dry condition this is so easily oxidized that it ignites spontaneously. In a vacuum at 500°

¹ *Z. anorg. Chem.* **86**, 296.

² *Ber.*, **47**, 810.

³ *Ibid.*, 3113, 3115.

potassium hypoborate loses $\frac{2}{5}$ of its potassium, which distils off, while hydrogen is also evolved, and a residue with the formula $K_3B_5O_8$ remains, which is probably not a definite compound. In both potassium hypoborate and the nickel boride, the boron is evidently quadrivalent. For reaction with the halogens H_6B_2 was chosen, as being the simplest of the borides of hydrogen. When an excess of chlorine or bromine is used, the resultant product is BCl_3 or BBr_3 , but, by using smaller proportions of the halogen, evidence of the formation of intermediate compounds was obtained, and B_2H_5Br was isolated. B_2H_5Cl is probably a spontaneously inflammable gas. It seems also probable that $B_2H_4X_2$ and $B_2H_3X_3$ may exist, but break up into B_2H_6 , B_2H_5X , and BX_3 . No evidence could be found for the existence of any of the partially halogenated compounds with a monomolecular formula, as BH_2X or BHX_2 ; nor do any more highly halogenated compounds, such as $B_2H_2X_4$ or B_2HX_5 , appear capable of existence. Further, neither BCl_3 nor BBr_3 will take on more of the halogen. While these results which Stock has obtained in boron compounds are altogether unexpected, yet they are not really anomalous. Theoretically, the maximum positive valence of boron is three, and this has not been exceeded in any of these compounds. The maximum negative valence is five, and in the hydrogen borides of Stock it reaches four, and the compounds appear to have similar constitutions to some of the compounds of carbon and hydrogen, as H_6B_2 and $H_{10}B_4$, boroethane and borobutane. In boroethane the hydrogen is replaceable by halogens, as in ethane; when fully replaced, the boron being now positive to the chlorine, or bromine, the B_2Cl_6 spontaneously breaks down into 2 BCl_3 .

The compounds of boric acid with thallium have been studied by Buchtala.¹ No compounds with trivalent thallium could be obtained, but the thallous borates are formed by solution or fusion of thallous carbonate or hydroxide with boric acid. The series from $Tl_2O \cdot B_2O_3$ to $Tl_2O \cdot 6B_2O_3$, with varying quantities of water, was prepared, and the members resemble the borates of the alkalis except in their water content. All these thallous borates give with hydrogen peroxide a perborate, with formula $Tl_2B_2O_7$, which decomposes explosively on heating, and on warming with water evolves three atoms of oxygen. To this perborate Buchtala

should consider the two boron atoms to be linked together.

The fourth paper of R. J. Meyer² on scandium presents several points of interest. The most characteristic distinctions between scandium and the other "earths" depend upon its more negative character. From this follows the strong tendency of its salts to hydrolysis, and also to form complex ions. In its hydrolytic tendency scandium resembles aluminum; its chlorides and nitrates in solution are weakly acid, and when heated are partially precipitated by sodium acetate, and completely by sodium

¹ *J. prakt. Chem.*, [2] 88, 771.

² *Z. anorg. Chem.*, 86, 257.

thiosulfate. The solution of the sulfate is only incompletely precipitated, owing to the formation of complex salts. In this tendency to form complex ions scandium resembles zirconium and thorium, indeed, in many respects it stands chemically quite close in its properties to thorium. It is distinguished from aluminum by not being amphoteric. Double chlorides of scandium and the alkalis could be realized only in the case of cesium, as seems to be the case also with several of the rare earth metals. Double fluorides are, however, formed, as K_3ScF_6 . Scandium sulfate is the scandium salt of a scandium-sulfuric acid, $H_3(Sc(SO_4)_3)$, of which also the alkali salts, as $K_3(Sc(SO_4)_3)$, were prepared. This constitution is confirmed by the work of Wirth,¹ who by dissolving scandium sulfate in sulfuric acid obtains white crystals of the formula $Sc_2(SO_4)_3 \cdot 3H_2SO_4$, which is in reality the above-mentioned scandium-sulfuric acid. Wirth also finds that when scandium sulfate is heated in dry H_2S the sulfide Sc_2S_3 is formed, which is fairly stable in dry air. Among the other salts investigated by Meyer are the oxalates, and here also, like thorium, scandium forms complex anions. The complex oxalates of the formula $R'Sc(C_2O_4)_2$, are very stable and only slowly decomposed, even by sulfuric acid. These oxalates have also been studied by Wirth, who has prepared salts of the scandium-oxalic acid, $H_3(Sc(C_2O_4)_3)$, and it appears that scandium oxalate itself, $Sc_2(C_2O_4)_3 \cdot 5H_2O$, is in reality the scandium salt of this acid. Among other recent workers on scandium is Lukens,² who has separated it from the residues of Colorado wolframite, and determined its atomic weight from the sulfate-oxide ratio; and Sterba-Böhm,³ who has purified scandium by the fractionation of the formate. From this work the latter concludes that scandium is a simple element. He has also investigated the rose-colored sulfide supposed by Ogawa to contain a new element, and finds that it consists exclusively of sulfur and copper sulfide.

Group IV.—Lely and Hamburger⁴ have prepared metallic titanium, zirconium, thorium and uranium in a state of very considerable purity (uranium 99.5% pure) by the reduction of the chlorides by metallic sodium. The anhydrous chlorides were in general formed by the action of carbon tetrachloride or the chloride of sulfur in a chlorine atmosphere. Metallic titanium is less ductile than the other metals and the pulverulent metal can be formed into coherent masses only with great difficulty. It is also much less resistant to reagents. Zirconium was obtained in large metallic leaflets and easily gave a metallic mirror by rubbing in an agate mortar. While more easily oxidized than titanium, it is much more resistant to acids and alkalis, though readily attacked by hot *aqua regia* or oil of vitriol. Hydrofluoric acid, even when dilute, attacks it rapidly in the cold. Metallic thorium is lead-gray, and very stable in the air, as well as toward alkalis in solution and nitric acid. In hydrochloric acid hydrogen is evolved, but the metal does not dissolve completely. By *aqua regia* thorium is oxidized to ThO_2 . Metallic uranium is darker than thorium, but quickly colors brown in the air. It is not attacked by water or alkaline solutions, nor by acetic acid. In dilute hydrochloric acid hy-

¹ *Z. anorg. Chem.*, **87**, 1, 7, 9.

² *THIS JOURNAL*, **35**, 1470.

³ *Z. Elektrochem.*, **20**, 289.

⁴ *Z. anorg. Chem.*, **87**, 209.

hydrogen is evolved and UCl_4 formed, but in the concentrated acid the metal quickly dissolves to a violet-colored solution of UCl_3 , which, however, slowly goes over into green UCl_4 . The metal dissolves rapidly in nitric acid with the formation of uranyl nitrate.

Group V.—The question of the existence of an active form of nitrogen has continued to attract the attention of several chemists during the past year. Strutt first called attention to the orange-yellow cloud-like luminescence observed when the electric discharge is passed through nitrogen at pressures from 1 to 10 mm., and ascribed it to an active modification of the nitrogen. In this gas many elements and compounds are acted on with the formation of nitrogen compounds. This was first contested by Comte, who claimed that the luminescence was due to the presence of traces of oxygen, and the compounds to a nitrogen oxide. Tiede and Domcke¹ have repeated a second time Strutt's experiments, using every precaution to free the nitrogen from traces of oxygen and to avoid any possible access of this gas. By adding traces of oxygen the luminescence appeared, by its withdrawal the luminescence was reduced to a minimum. If too much oxygen is added the luminescence disappears. From this the conclusion is drawn that so far from being a proof of the existence of active nitrogen, the luminescence is a sensitive reagent for traces of oxygen in nitrogen. Fischer² agrees with Tiede, and ascribes the phenomena to the activation of the traces of oxygen rather than to the nitrogen. These conclusions are disputed by Koenig and Hlöd,³ by Baker and Strutt,⁴ by Strutt⁵ and by de Kowalski.⁶ According to the first, the luminescence is to be looked upon as an accompaniment of active nitrogen, not as proof of its existence. This is proved by its reactions at ordinary temperatures with substances which do not react with nitrogen in its common form. Among many other substances, pentane, carefully purified from all unsaturated hydrocarbons, reacts with active nitrogen, giving amylene, ammonia and a trace of hydrogen cyanide. Not only nitrogen is capable of being thus activated, but pure oxygen gives a modification more active than ozone and this phenomenon is also accompanied with luminescence. Since metallic vapors destroy or inhibit the luminescence of nitrogen, the failure of Tiede to obtain luminescence in his pure nitrogen is attributed to the presence of mercury vapor, or of the metals from the azides which he used to furnish his nitrogen. de Kowalski also obtains the luminescence in nitrogen enclosed in a glass globe in an induced electric field. The work of the others is all confirmatory of the original work of Strutt, but the large volume of exceedingly interesting experimental work must be passed over in this review, which has aimed to touch on only the most salient points.

An apparently successful attempt to solve the problems which surround the conditions of existence of nitrogen sesquioxide has been made by Klinger.⁷ He finds that dry N_2O_3 is rapidly and quantitatively absorbed

by dry caustic potash. Enclosing sticks of dry caustic potash in a measured excess of dry oxygen, in a pipet, he added a measured quantity of NO. The diminution of volume was $\frac{5}{4}$ that of the NO added, corresponding to the equation: $4\text{NO} + \text{O}_2 = 2\text{N}_2\text{O}_3$. Had NO_2 been formed, the diminution would have been $\frac{3}{2}$ corresponding to: $2\text{NO} + \text{O}_2 = 2\text{NO}_2$. From this the conclusion is drawn that oxygen does not unite directly with NO to form NO_2 , but that N_2O_3 is formed as an intermediate product. Again, NO_2 is instantly absorbed by caustic potash to a mixture of nitrite and nitrate, while NO does not form any compound instantaneously. A mixture of equal molecules of NO and NO_2 was immediately and completely absorbed by caustic potash with the formation of potassium nitrite, consequently no NO or NO_2 , as such, could have been present, or some of the NO would have been left over, and some nitrate formed. It follows that a mixture of NO and NO_2 must be looked on as N_2O_3 .¹ Several years ago Raschig described a new oxide of nitrogen formed by leading NO into liquid air, and ascribed to it the formula NO_2 . This has been disputed by Müller, and Raschig has repeated and extended his work.² The compound is also formed, as noted by Müller, by a high-tension electric flame in liquid air, and is a light green precipitate, becoming a dull gray-blue as the oxygen evaporates. The compound cannot be N_2O_3 , as was contended by Müller, since this is deep indigo-blue, both in solid and in liquid form. On the evaporation of the liquid air there is left at -110° a dull blue solid, which breaks up at -100° , and which has the formula NO_2 . Since it possesses none of the ordinary properties of NO_2 or N_2O_4 , it must be an isomer, and Raschig calls it iso-nitrogen tetroxide. The dull green compound from which the iso-tetroxide is formed, after washing with liquid nitrogen is nitrogen hexoxide, NO_3 . Raschig's work is again criticized by Müller,³ who claims that the supposed NO_3 is merely a mixture of NO_2 , N_2O_4 , N_2O_3 and NO, and that on washing with liquid nitrogen it loses no oxygen, and no iso-tetroxide is formed. Mention should be made of a very complete investigation of nitrites, their conditions of formation and decomposition, by Oswald,⁴ which however, does not admit of useful abstraction. Ball⁵ has continued his study of bismuth nitrites, and prepared a large number of new salts, in which the tendency of bismuth to form triple nitrites is very apparent. Of the fifteen possible salts of the formula $\text{X}_2\text{YBi}(\text{NO}_2)_6$, where X = NH₄, K, Rb, Cs, Tl', and Y = Li, Na, Ag, all were prepared. Of triple nitrites with nickel, $\text{K}_4\text{NiBi}_2(\text{NO}_2)_{12}\text{.aq.}$ and the corresponding thallium salt (anhydrous), were obtained, and also $\text{Rb}_7\text{NiBi}_3(\text{NO}_2)_{18}\text{.4H}_2\text{O}$ and the corresponding cesium salt with 6 H_2O . There would seem to be still considerable field for investigation among the curious triple nitrites, which, except by Ball, has hardly been touched since the work of Przibylla on the triple nitrites of nickel. In his work upon the compounds of nitric oxide on salts of iron and copper, Manchot⁶ has, for the first time, prepared

¹ The density of the mixture demonstrates that at ordinary temperature N_2O_3 dissociates almost completely into NO and NO_2 . —EDITOR.

a ferrous-nitric oxide compound of the brown series in a solid crystallized condition. A solution of ferrous chloride in alcohol was saturated with NO and kept in an NO atmosphere. This was precipitated with an alcoholic solution of di-ammonium hydrogen phosphate, a thick oil separating out, which became crystalline at -15° . The compound is $(\text{FeNO})\cdot\text{HPO}_4$, is fairly stable, fuses at $+16^{\circ}$, and in it there is present one molecule of NO to each Fe atom. It is oxidized rather slowly in the air or when shaken in water, gradually losing its very dark brown color and becoming white; in concentrated sulfuric acid it dissolves to a deep red solution. Similar salts are obtained with other inorganic acids, but not with organic. Thus, while oxalic acid gives with ferrous solutions an insoluble ferrous oxalate, if the solution is saturated with nitric oxide there is no precipitate, the ferrous-nitric oxide oxalate being very soluble. In these compounds there is present the bivalent kation $(\text{FeNO})^{++}$. The reaction of cupric chloride and bromide with nitric oxide does not seem to be characteristic of bivalent copper in general, since there was found to be no absorption of nitric oxide in solutions of the fluoride, nitrate, acetate, formate, amidoacetate, and other cupric salts in absolute alcohol. The NO in $\text{CuBr}_2\cdot\text{NO}$ is so sensitive to the presence of water that it would seem that there is a competition between the H_2O and NO molecule for the available addition-position. The action of nitrogen and hydrogen on the alkaline earth metals has been studied by Dafert and Miklausz,¹ the strontium and barium being obtained by distilling a mixture of the oxide with aluminum in a vacuum, and the calcium by redistilling commercial calcium. Metallic calcium begins to react with nitrogen at about 400° , while strontium reacts somewhat lower and barium at 260° . In each case the nitride M_3N_2 is formed. These nitrides begin to absorb hydrogen at 230° 300° ,—calcium at the lowest temperature—with the formation of a trimetallamide, $\text{M}_3\text{N}_2\text{H}_4$. In the case of calcium an intermediate product is formed, which is probably tricalciumimide, $\text{Ca}_3\text{N}_2\text{H}_2$, which is especially sensitive to the light. Barium nitride on absorbing hydrogen gives off nitrogen, partly as ammonia. The substance produced is scarcely sensitive to light, and is of interest because at $700\text{--}750^{\circ}$ it absorbs nitrogen with evolution of hydrogen, and then at $300\text{--}400^{\circ}$ in a current of hydrogen gives off the nitrogen again, partly as ammonia. These reactions present possibilities of being utilized for the commercial production of ammonia from nitrogen and hydrogen. Calcium reacts with hydrogen at 300° , with strontium the reaction begins at 215° , and with barium at 120° . In each case the hydride, MH_2 is formed. Somewhat below a red heat these hydrides absorb nitrogen, the first two giving the imides CaNH and SrNH , but with barium hydride no imide is formed. At higher temperatures nitrides are obtained. A relatively pure calcium imide, which is very sensitive to light, is formed by heating calcium hydride, or better, calcium nitride to $730\text{--}750^{\circ}$ in a stream of equal parts hydrogen and nitrogen.

In the course of a paper on the characteristics of the different modifications of phosphorus² Stock and Stamm consider the question as to whether the vapors of yellow and red phosphorus are identical. Red phosphorus, distilled from the hot to the cold end of an evacuated tube at $280\text{--}400^{\circ}$, condenses always in small part to red phosphorus again,

¹ *Monatsh. Chem.*, **34**, 1685.

² *Ber.*, **46**, 3497.

while both the yellow phosphorus and the Hittorf modification give colorless distillates. From this and other experiments, it is concluded that in vapor from red phosphorus there are actually present red phosphorus molecules, but that their concentration is exceedingly small. The chief constituent of the vapor of phosphorus of any kind is P_4 , which dissociates to a slight extent,—10.5% at 900° and 120 mm.—into P_2 . The equilibrium: $P_4 \rightleftharpoons 2P_2$ is displaced by decreasing pressure and increasing temperature in favor of P_2 ; the equilibrium: $xP_2 + yP_4 \rightleftharpoons P_{2x+4y}$ (red phosphorus vapor) is by decreasing pressure and increasing temperature displaced against the red phosphorus.

Group VI.—An investigation of the polysulfides of sodium was carried out by Rule and Thomas¹ in absolute alcohol. Metallic sodium was dissolved in alcohol and then saturated with H_2S and the excess of gas removed by a stream of hydrogen, while the solution was on a water bath. In this solution of $NaSH$, aliquot atomic quantities of sulfur were dissolved, and the solid product obtained by evaporation, or cooling, or both. The only pure compound which could be obtained was the tetrasulfide, Na_2S_4 . There was evidence of the existence of a higher polysulfide, but none could be isolated. The tetrasulfide is therefore to be looked on as the chief product of the action of sulfur on sodium hydrosulfide in alcoholic solution. By the action of metallic sodium the tetrasulfide is reduced (in alcohol) to the disulfide, Na_2S_2 , which is obtained as a microcrystalline powder, while sodium hydrosulfide remains in solution. It has long been a puzzle why nickel and cobalt sulfides, which are not soluble in acids, should not be precipitated from acid solutions by hydrogen sulfides. Two explanations have been offered: (1) The sulfides are insoluble, but their non-precipitation in acid solutions is due to a persistent supersaturation; (2) the sulfides are primarily precipitated in a form soluble in acids, which rapidly passes over into an insoluble form ("by polymerization"). Two other complications offer themselves, in that on long standing hydrogen sulfide does sometimes precipitate nickel sulfide, and the precipitated sulfides are generally, especially when freshly precipitated, far from completely insoluble in hydrochloric acid. The problem in regard to nickel sulfide has been attacked, with seeming success, by Thiel.² He finds that nickel sulfide when freshly precipitated is a mixture of three modifications, which he calls α , β , and γ , all of which have the formula NiS . αNiS is rapidly soluble in dilute HCl , but gradually passes over into the β and γ forms on standing, especially with access of air. It is predominately precipitated when dilute nickel solutions are slowly added to dilute alkali sulfide solutions in the cold and without access of air. In such cases it may be present in the precipitate to the extent of 85%. It is possible to wash it, dry it with alcohol, warm, and even heat it to red heat without its being completely converted into the other modifications. βNiS is very slightly soluble in cold HCl , but dissolves slowly in hot 2*N* acid. It is converted into γNiS by boiling several hours with 2*N* acetic acid. It is precipitated free from αNiS and with but little γNiS by H_2S from a hot solution of nickel acetate with excess of acetic acid. γNiS is insoluble in cold 2*N* HCl , and its solubility in the hot acid is very slight (0.0013 g. in 100 cc.). It remains as residue when a precipitated NiS

¹ *J. Chem. Soc.*, 105, 177.

² *Sitzber. med.-naturwiss. Ges. Münster*, 1913.

is extracted with hot HCl, in the form precipitated by H_2S after long standing from solutions not too strongly acidified with mineral acids, and into this the other forms are converted by boiling with acetic acid. β and γ forms are obtained when H_2S acts on nickel carbonate or hydroxide, and this explains the action of the air in converting the α modification into these forms; the air oxidizes the α NiS to the hydroxide and this is secondarily converted into the β and γ NiS by an excess of hydrogen sulfide. These changes seem clearly to be polymerization processes.

Several years ago Rosenheim prepared complex molybdenum cyanides with the formula $\text{M}_4'\text{Mo}(\text{CN})_8$, the only known compound in which eight coördinated groups surround the central atom. In these compounds the molybdenum appeared to be quinquivalent, so that the compound does not seem to accord with the ordinary valence rules. He has now¹ prepared analogous tungsten cyanides which correspond in every way to those of molybdenum, and in which the tungsten, as determined by titration with KMnO_4 , is also quinquivalent. The $(\text{W}(\text{CN})_8)^{\text{iv}}$ group is even more stable than the ferrocyanide group, and the free acid can be prepared. Apparently independent of Rosenheim's work, Olsson² has prepared these same tungsten octocyanides, but he differs from Rosenheim regarding the valence of the tungsten atom, holding that it is quadrivalent, as would be expected. The results of the permanganate titration he explains by assuming that instead of being oxidized to WO_3 , the tungsten forms a complex in which its valence reaches only five. A fuller description is later given³ by Olsson, and he has succeeded in isolating the complex of quinquivalent tungsten, formed by oxidation with KMnO_4 , and in preparing the series of salts $\text{M}_3'\text{W}(\text{CN})_8$, in which the tungsten is quinquivalent.

Group VII.—As a method of preparing anhydrous chlorides, Conduché⁴ proposes heating sulfates, which have already been rendered anhydrous, in a current of dry carbon dioxide and chloroform. The reaction with CuSO_4 begins at 250° , with NiSO_4 and FeSO_4 at 300° , and with other sulfates at slightly higher temperatures, BaSO_4 and CaSO_4 reacting at 500° . At 280 – 300° by this method CuCl_2 is easily obtained in a pure and anhydrous condition. At a higher temperature CuCl is also formed, the reducing action of the chloroform coming also into play. The chloroform acts like a mixture of chlorine and hydrogen chloride and different chlorides of the same metal may be formed at different temperatures. In the case of iron, whether one starts from ferrous or ferric sulfate, both ferrous and ferric chloride are obtained, and can be readily separated by the sublimation of the latter.

Group VIII.—Bellucci and Corelli have continued their efforts⁵ to isolate the double cyanide of univalent nickel, described last year. By the reduction of $\text{K}_2\text{Ni}(\text{CN})_4$ solution with potassium amalgam in a hydrogen atmosphere, they obtain a dark red solution from which alcohol precipitates an exceedingly unstable, dark red, oily substance, which when dissolved in water gives the ratio $\text{Ni} : 3\text{CN} : 2\text{K}$, and which on titration

¹ *Ber.*, 47, 392.

² *Ibid.*, 917.

³ *Z. anorg. Chem.*, 88, 49.

⁴ *Compt. rend.*, 158, 1180.

⁵ *Atti accad. Lincei, Rome* [5] 22, ii, 485.

with iodine takes up one atom of iodine for each atom of nickel. This establishes the formula, as was expected, as $K_2Ni(CN)_3$, or $2KCN.NiCN$, the complex containing nickel in a univalent condition. Tschugejew and Chlopin¹ have also obtained univalent nickel by the reduction of nickel salts by a concentrated solution of sodium hydrosulfite and nitrite in equimolecular proportion. A violet or blue coloration is produced according to the amount of reagent used. The violet solution contains $HN(NiSO_3)(HSO_3).nH_2O$, which could not, however, be obtained in a completely pure condition. Sodium hydroxide gives a blue precipitate of what is apparently $NiOH$, but which could not be dried without decomposition. This is converted by sodium sulfide into black Ni_2S , which can be isolated only in moist condition. The blue hydrate dissolves in KCN to a red solution, which seems to be identical with that of Bellucci's $K_2Ni(CN)_3$.

Barbieri² has entered on a systematic study of resemblances between compounds of elements in different groups of the periodic system, when these elements have the same valence. Thus an element of the eighth group, acting with a valence of three, may be, for practical purposes, considered as an element of the third group. As examples he has prepared Ruthenium acetylacetonate, $Ru(C_5N_7O_2)_3$, and finds it to closely resemble aluminum acetylacetonate, with which it is isomorphous and gives solid solutions. Ammonium rhodio-molybdate, $3(NH_4)_2O.Rh_2O_3.12MoO_3.20H_2O$, is in every way similar to the corresponding Al , Fe''' , and Cr''' salts, as well as to the Co''' salt of Friedheim and Keller. The isomorphism of palladium acetylacetonate with the corresponding cupric salt was shown by the formation of solid solutions. Delépinc³ has succeeded in preparing the very soluble chloro-iridates and iridites of lithium. Li_2IrCl_6 crystallizes as a hexahydrate, and when crystallized with sodium chloro-iridate does not form any intermediate compound. When reduced by alcohol $Li_3IrCl_6.12H_2O$ is formed and hydrogen chloro-iridite remains in the mother liquor. No intermediate lithium-hydrogen salt is formed. Better results are obtained by reducing the lithium chloro-iridate with lithium oxalate. By mixing with solutions of sodium chloro-iridite, the intermediate compounds, $Na_2LiIrCl_6.12H_2O$ and $Na_{1.1}Li_{1.9}IrCl_6.12H_2O$, were obtained, but when recrystallized from water the sodium salt resulted, containing very small quantities of lithium. Fraenkel has prepared⁴ a number of new salts of rhodium and iridium with organic bases. Chloro-iridic acid gave only the familiar type, $M_2'IRCl_6$. With rhodium, however, not only the type $M_3'RhCl_6$ was obtained, but also $M_2'RhCl_6$ (with methylamine), $M_4'RhCl_7$ (with methylamine and tetraethylamine), and $M_3'Rh_2Cl_9$ (with trimethylamine and tetraethylamine).

NOTE.

A Surfaceal Burn Produced by an Unknown Radiation.—Woehler,⁵ in 1862, heated carbon and an alloy of calcium and zinc together and

¹ *Compt. rend.*, 159, 62.

² *Atti accad. Lincei, Rome* [5] 23, i, 334.

³ *Compt. rend.*, 158, 1276.

⁴ *Monatsh. Chem.*, 35, 119.

⁵ F. Woehler, "Bildung des Acetylens durch Kohlenstoffcalcium," *Ann. Chem. Pharm.*, 124, 220 (1862).

obtained a product which evolved acetylene when treated with water. He called the product calcium carbide.

The alloy had been previously described by Caron,¹ who got it by adding metallic sodium to fused calcium chloride in the presence of molten zinc. This alloy is of silvery luster, highly crystalline, and contains from 10% to 15% calcium.

On repeating Woehler's experiment, in connection with other experiments on making calcium carbide by different methods, use was made of a gas crucible furnace of present day type. The objection was raised that a temperature was thus secured higher than that Woehler probably worked with. Accordingly, an old-fashioned assay furnace of French clay, which had come to me as an heirloom, was set up. This furnace was in three sections, the lower one having a grate and ash pit, the second section being merely a ring, and the third, or top section being dome shaped, and having a central round opening on top which was connected to a wide chimney by means of a sheet iron smoke stack.

Caron alloy was made by melting lumps of fused C. P. calcium chloride and granulated zinc, 20 mesh, in a Dixon graphite crucible and adding slices of metallic sodium. The reaction is at times violent. There results on cooling a fine regulus of the calcium zinc alloy. Charcoal was used as fuel.

Separate portions of this alloy were made at different times and heated with different varieties of carbon, such as charcoal, coke, lampblack and gas carbon, a sample of the latter dating from 1850 to 1860 being found among apparatus left me.

On Nov. 30, 1907, two charges were run in the furnace. In the first, use was made of alloy and gas carbon, in the second alloy and lampblack. The operation was conducted with 1100 g. of a 14% alloy and 110 g. of lampblack, using a No. 6 Dixon crucible. It took three hours to distill off the zinc, during which time I sat with the furnace between my knees feeding in the charcoal used as fuel through a side opening in the stack. Though the work was somewhat dirty no inconvenience was felt at the time. Later on, undressing for a bath, the inner surface of each knee was found red, and there was a water blister, about 1 cc. in diameter, in the center of the red surface on the left knee. The red patch was about the size of my hand, that on the right knee half that size.

Since this effect had been produced not only through a pair of thick trousers but thick woolen drawers under them, without my noticing any sensation, and as the burn appeared like one made by X-rays, with which I was familiar, it was later shown to Drs. Robert Abbe and Henry G. Piffard, both of whom were familiar with X-ray and radium burns and they agreed with my diagnosis, and considered the burn was similar in character to burns produced by those agencies.

¹ H. Caron, *Compt. rend.*, 50, 547 (1860).

The nature of the burn was further confirmed by the fact that it took long to heal, traces of it were visible Mar. 31, 1908, or four months later.

To further test the theory, at Dr. Abbe's suggestion, the experiment was repeated on Dec. 21, and to eliminate the personal equation a sheet of lead, perforated with five holes, was interposed between the Cramer X-ray "X" plate, enclosed in the usual black and yellow papers, and the portion of the furnace corresponding to the height of my knee from the floor, while the zinc was distilled. There is a crack around the furnace at this point, and it was about there that the fumes of burning zinc could be seen within the furnace. Alloy and lampblack were again used in the charge. The plate was exposed for 1 hr. and 17 min. at a distance of 2 ft. from the furnace, and a thermometer placed beside the plate showed a temperature ranging from 25° to 35° , with one time a temperature of 42° .

The plate was given to a photographer to be developed along usual lines, but he was not told what might appear on the plate. The developed plate and a positive printed from it show the five holes in the lead covering plate and thus confirm the diagnosis of the nature of the burn.

Later, other plates were exposed during runs but no distinct effects produced. Nor was there any similar result to the first obtained when Messrs. Stone and Riggs kindly exposed similar plates behind the perforated lead plate to the light of burning zinc at the furnaces of the New Jersey Zinc Company.

Both the burn and the effect on the X-ray plate were produced when alloy and lampblack were used. When coke, charcoal, and gas carbon were used with the alloy no photographic evidence was obtained. The lampblack was purchased in open market, as also the zinc, calcium chloride, and sodium, the other chemicals used. The fuel was either ordinary charcoal or in the later experiments coke or coal or both together. The Dixon crucibles and covers were new.

As an opportunity has not presented itself for me to repeat these experiments methodically and determine the cause of the phenomena the facts are placed on record in the hope that sometime an explanation will be forthcoming.

CHARLES A. DOREMUS.

THE INFLUENCE OF TEMPERATURE IN ACID CATALYSIS.

BY HUGH STOTT TAYLOR.

Received December 21, 1914.

Since the suggestion was put forward by Goldschmidt,¹ Snethlage²

¹ *Z. physik. Chem.*, **70**, 627 (1910); **81**, 30 (1912).

² *Z. Elektrochem.*, **18**, 539 (1912); *Z. physik. Chem.*, **85**, 211 (1913).

and Acree¹ that, in addition to the hydrogen ion, the undissociated molecule of an acid has a catalytic effect, interest in reactions catalyzed by acids has been markedly stimulated. Snethlage amplified the observation by calling attention to the fact that the stronger the acid, or the greater its dissociation constant, the more active was the undissociated molecule catalytically as compared with the hydrogen ion.

In a series of researches the author, acting upon the above suggestion, showed that the theory was quantitatively applicable, in addition to the catalytic reactions of acids in organic solvents as studied by the investigators cited above, to reactions in aqueous solutions. The first investigation² showed that neutral salt action in ester catalysis was independent of the ester substrat, that, therefore, the existence of an equilibrium of active and inactive molecules of the ester substrat, such as had earlier been suggested by Arrhenius to account for the high temperature coefficient of such reactions, was rendered improbable and that an explanation of neutral salt action would probably be such as involves only the catalyzing liquid and not the ester present.

It was next shown³ that the experimental results of simple acid catalysis and of the accelerating influence of neutral salts in aqueous solutions could be interpreted more closely than was hitherto possible, and with an accuracy as considerable as the present fairly large experimental error will permit, if the activity of the undissociated molecule be assumed. Also, the relation of Snethlage between activity and strength of acid was shown to be applicable in aqueous solutions.

These conclusions received independent confirmation in a research of Dawson and Powis⁴ on the catalytic influence of acids on the keto-enol transformation of acetone in aqueous solutions. With the aid of the then available literature the author was led⁵ to the formulation of a quantitative relation between catalytic ratio of undissociated molecule and hydrogen ion activities and the affinity constants of various acids. It was suggested that a simple mathematical relationship, *viz.*, that the affinity constant was equal to the square of the catalytic ratio, existed between the two; that the strength of the acid is the primary factor in the determination of the catalytic ratio and that deviations from the values calculated according to the equations deduced in the paper should be sought for in the variations of the nature of the reaction studied.

Somewhat later,⁶ MacBain and Coleman, in a recalculation of some old data of Arrhenius on the dissociation of weak acids, called attention to the

fact that some measurements of Arrhenius on the inversion of cane sugar by hydrochloric acid, in presence and absence of potassium chloride at varying temperatures, could be used for the determination of the ratio $K_m : K_h$.¹ These data, while revealing internal evidence of a certain amount of experimental error, made it appear probable, according to the authors, that the ratio K_m/K_h decreases with rise of temperature. The actual figures are given in Table I.

TABLE I.

Potassium chloride.	0.05N HCl at 25°.	0.01N HCl at 38°.	0.0005N HCl at 52°.
0.025	2.99	1.45	1.13
0.125	2.77	1.70	1.30

It was further suggested that this effect had not hitherto been suspected and might serve to explain some of the deviations from the quantitative relationship proposed somewhat earlier by the author. Actually, however, the point in question had been noted and the same calculations had been made with essentially the same result, but it was felt that, in view of the extraordinary sensitivity of the ratio to small experimental errors as evidenced by the author's own results under more favorable conditions, it would be better to defer discussion of the point until some more definite evidence was accumulated. Certain experiments were, however, carried out in the laboratory of Arrhenius by the author having a bearing on the point in question, which will be presented below, together with other experimental data just available from the literature. MacBain and Coleman nevertheless point out later in their paper that, if a constant value for K_m/K_h of 1.5 is applied throughout their calculations for all temperatures, all the results with the exception of the first three are within 4% of the predicted rates; and that of the three discordant experiments one diverges as much in one direction as another does in the opposite. It is obvious, therefore, that a decision as to whether the catalytic ratio is a variable with temperature remained, as a result of MacBain and Coleman's investigations, an open question.

There has recently appeared² a paper on catalysis which supplies data utilizable for a calculation of the temperature influence in ester catalysis as regards the catalytic ratio. The hydrolysis of methyl acetate at vary-

¹ The reaction constant is regarded as due to the sum of two catalytic activities, that of the hydrogen ion K_h and that of the undissociated acid K_m . These activities are regarded as operating in degrees proportional to their concentrations as calculated from the conductivity data. An equation is obtained of the form

$$n_h K_h + n_m K_m = R$$

where n_h or n_m are the respective concentrations of ion or molecule, R the reaction constant. From two such equations K_m and K_h may be evaluated and the catalytic ratio, $K_m : K_h$ obtained.

² Lamble and Lewis, *J. Chem. Soc.*, 105, 2330 (1914).

ing concentrations of hydrochloric acid has been studied at 25° and 35° and the degrees of dissociation and hydrogen ion concentrations of the acids employed have been obtained. The range of concentrations chosen was large and the data obtained seemed to offer a good opportunity for making the calculations required. The general conclusion is drawn that there is no tendency at all for the temperature-coefficient of a strongly catalyzed reaction to be less than that of a weakly catalyzed reaction, a deduction contrary to what one would have expected on the conception of active and inactive molecules of ester substrat, in agreement, therefore, with the earlier conclusions of the author from work on neutral salt action with varying ester.

The experimental results of Lamble and Lewis have been calculated to give the values of K_m and K_h and the ratio K_m/K_h at the two temperatures employed. The method of calculation has been described in detail in various earlier communications so that it calls for no further detailment here. The six possible combinations of pairs of data as to molecular and ionic concentrations and to catalytic activity at each temperature have been calculated and the results are set forth in Table II.

TABLE II.

							2 & 4	0.945	.77
							3 & 4	-0.71	.95

If the theory of Goldschmidt, Snethlage and Acree be correct, it is obvious that the ratio K_m/K_h as calculated from a series of acid dilutions should be constant. Observation will show that at 35° with one exception, in which experimental errors would certainly be greatest in their effect on the calculation, the requirement is fulfilled. At 25° it will readily be seen that the values obtained are by no means constant. Closer examination reveals, however, that only those calculations in which Expt. 3 was utilized were the deviations considerable, yielding in the one case a negative result. The experimental results were therefore examined more closely and led to the conclusion that in all probability some fairly considerable error had crept into the determination. For example, it is well known—and the data of Lamble and Lewis confirm this—that the reaction constant in catalysis of esters by hydrochloric acid increases at a slightly more rapid rate than does the normality of the acid; in other words, the

graph of the two sets of values yields a curve concave towards the axis of normality. Lamble and Lewis' results were plotted therefore in this manner and the plot for Expt. 3 was found to lie some considerable distance from the curve through the remaining points and concave to the axis of normality. Fortunately a determination made by the authors at a concentration 0.1024 *N* could be included to facilitate this conclusion. Further, an examination of the values used for the degree of dissociation at the concentration employed in Expt. 3, *viz.*, 1.80 *N*, showed the rather surprising result that the degree of dissociation at 1.80 *N* was equal to that at 1.28 *N* and amounted to 0.7900, while at a concentration 0.6 *N* higher the dissociation had fallen rapidly again to 0.7071. It is not surprising, therefore, that with two such factors operating in the calculations the results obtained should show some irregularity. Of the remaining three it cannot be said, however, that they show values higher than those obtained in the calculations at 35°. The mean of the three calculations at 25° is 1.75 while of the five concordant values at 35° the mean is 1.81.

Happily, however, a surer test than the above may be applied to the question of the variability or non-variability of the ratio K_m/K_h with temperature. Dawson and Powis obtained in their investigations a most excellent series of values for K_m and K_h at 25° with hydrochloric acid, yielding as a mean value from a series of seven observations 1.77 for the catalytic ratio. This value is in remarkably good agreement with the value calculated from the data of Lamble and Lewis at the two temperatures.

It would seem, therefore, that the suggestion of MacBain and Coleman as to the decrease of the activity ratio with temperature is untenable in the light of the above results. Confirmation of this view seems forthcoming in the data presented below, compiled from experimental work of the author. In some earlier work on neutral salt action in ester catalysis it had been noted that, according to Price¹ and Senter² the action is not markedly influenced by temperature. That conclusion was tested experimentally by the author over a wider range of temperature than had previously been employed. The velocity of hydrolysis of ethyl acetate using 0.1 *N* hydrochloric acid, alone and in presence of normal potassium chloride, was studied at the three temperatures 0°, 25°, and 40°. The experimental values communicated below represent the means of at least two concordant experiments. The value *D* expresses the percentage increase in the reaction constant due to the presence of the salt, assuming that the change in the reaction constant is proportional to the change of hydrogen ion concentration.³

TABLE VI.

Temp.	Normality of acid.	Normality of neutral salt.	Velocity constant. K .	Hydrogen ion concentration, α .	$D = 100 \frac{K_1 - K_1 \alpha / \alpha_2}{K_1 \alpha / \alpha_1}$.
0°	0.10	...	2.056	0.916
	0.10	1.0	2.480	0.777	42.2
25	0.10	...	28.29	0.916
	0.10	1.0	34.45	0.777	43.6
40	0.10	...	109.4	0.916
	0.10	1.0	132.9	0.777	43.2

Assuming, therefore, as has frequently been shown, that at these concentrations the degree of dissociation of the acid varies but slightly with temperature, it is obvious that the values for K_m/K_h obtained at the various temperatures will also be concordant. In other words, as pointed out previously by the author, the ratio of the catalytic activities of undissociated molecule and hydrogen ion is primarily a function of the strength of the acid and therefore of its dissociation constant when such can be derived; that therefore, since the dissociation constant varies but little with temperature, the catalytic ratio will itself be relatively independent of temperature and not, as originally suggested by MacBain and Coleman, possess a large temperature coefficient.

Attention might here be directed also to the method employed by Lamble and Lewis for the determination of the temperature coefficient of these reactions. As pointed out by them, so long as the same hydrogen ion concentration persists at the two temperatures in the corresponding experiment, the concentration of the catalyst remains the same, whether the catalyst be the hydrogen ions, the undissociated molecules or both. But at the higher concentrations employed by them the condition is no longer fulfilled, for a hydrogen ion concentration of 1.422 corresponds to a 1.800 *N* acid at 25° and to a 1.935 *N* acid at 35°. It is evident, therefore, that if the undissociated molecule be considered active, then of the two solutions, at the same hydrogen ion concentration, the acid of normality 1.935 at 35° will be the more active, since its concentration will be 0.513 in respect to undissociated molecule, as compared with 0.378 in the case of the acid of normality 1.800 at 25°. Since the undissociated molecule appears from the previous calculations to be 1.8 times as active as the hydrogen ion, it is evident that the temperature coefficient K_{35}/K_{25} , as deduced by them, is in reality a little too large as the total concentration of catalyst is greater at the higher temperature. If this factor is taken into consideration, and the reaction constant at 25° be re-checked, it is very probable that the temperature coefficient K_{35}/K_{25} at the two higher concentrations would more closely correspond with the very concordant value found by them in the more dilute solutions, where no divergence exists between acid normality and hydrogen ion concentration at the two temperatures.

Summary.

An examination of recently available literature on catalysis of esters at varying temperatures, together with some new experimental data on neutral salt action in ester catalysis at 0°, 25°, and 40° is shown to yield the conclusion that the ratio of the catalytic activities of undissociated molecule and hydrogen ion does not possess a considerable temperature coefficient such as was suggested by MacBain and Coleman, but, on the contrary, is independent of temperature. The importance of a consideration of the activity of the undissociated molecule in calculations of reaction constants in acid catalyses has been emphasized.

PRINCETON, N. J.

ORGANIC OXONIUM COMPOUNDS.

I. DIMETHYLPYRONEHYDROCHLORIDE.

By H. N. K. RÖRDAM.

Received January 6, 1915.

Theoretical Part.

Since the discovery by Collie and Tickle¹ of the addition compounds of dimethylpyrone with acids, numerous investigations have been made upon this matter. That these and similar addition products of organic compounds containing oxygen are real and stable compounds and chemical individuals has been shown in researches by several authors, among many others recently by Kendall,² and Maas and McIntosh.³ As to their being oxonium compounds, the question is still open. Not one single experimental fact is known, which absolutely compels us to see in them anything more than molecular compounds in which the acid is bound in the manner that the water of crystallization is in crystallized salts. If the addition compounds with acids are true oxonium compounds, they must be salts; but although many observations have been made which may suggest a salt character, only evidence, not certainty, has been won. The conductivities of these compounds as well as the depression of the freezing point of their solutions have been measured by several investigators. It was found that their solutions were conductive, and that the freezing point was more depressed than the number of dissolved mols would account for. From these measurements constants of dissociation for dimethylpyrone as a base were calculated. It is, however, evident that the results would be the same if only dissociation into components, for instance for dimethylpyronehydrochloride after the scheme:

takes place in the solutions. To prove that dimethylpyronehydrochloride is a real salt it must first be proved that, besides the above-named

¹ *J. Chem. Soc. Trans.*, 1899, 710.

² *THIS JOURNAL*, 36, 1222.

³ *Ibid.*, 34, 1273 and 35, 535.

hydrolytic dissociation into components, also electrolytic dissociation of the hydrolytically undissociated part takes place in solutions according to the scheme:

This has not yet been proved.

Nevertheless in modern textbooks the quadrivalence of oxygen is often treated as a matter of fact equal to the pentavalence of nitrogen, but this is due to a wrong estimation of some experimental results, the essentials of which I shall hereby briefly summarize, the question being about as important a matter as the supplementing of the theory of valency.

Coehn¹ has by means of migration measurements tried to demonstrate the presence of the ion

in solutions of dimethylpyrone into hydrochloric acid (20% HCl). He found that dimethylpyrone was carried to the cathode, but in one of the two experiments which he made, the electrode spaces were separated from the rest of the solution by parchment membranes, so that it was not excluded that electric endosmose might have taken place. Therefore Coehn made another experiment without membranes. When the electrolysis was finished, the contents of the electrode spaces were removed, and phosphotungstic acid was added, whereby dimethylpyrone is precipitated. The precipitate was not isolated or determined in any way, as was the case in the first of the two experiments; the author only reports that it could be directly seen that there was more of it in the cathode room than in the anode space. The omission of weighing the precipitate deprives this investigation of its significance, and moreover, among others, Coehn² himself has shown that non-electrolytes also can migrate under the influence of the electric current. For instance, cane sugar in hydrochloric acid will migrate to the cathode without the conductivity of the acid being altered more than the trifle which is due to the alteration of viscosity of the solution.

Walden's³ investigations mainly include:

1. The depression of the freezing point in solutions of dimethylpyrone and of dimethylpyrone + hydrochloric acid in water. 2. The conductivity of picric acid in water and of picric acid + dimethylpyrone in water.

These two series of experiments showed that part of the acid (picric or hydrochloric) was linked to the dimethylpyrone, and from the results Walden calculates the constants of hydrolytic dissociation for the oxonium salt which I have put together in the following table under K^{I} and K^{II} .

¹ *Ber.*, 35, 2673.

² *Z. f. Elektrochemie*, 1909, 652.

³ *Ber.*, 34, 4185.

K ^I .	K ^{II} .	K ^{III} .
0.648	0.59	0.72
0.373	0.45	0.60
0.340	0.53	0.62
...	0.50	0.52
Average..... 0.45	0.52	0.61

These constants have been calculated under assumption of electrolytic dissociation. Thereafter also an electrolytic dissociation constant for dimethylpyrone as a base is calculated by means of the equation:

$$K_{\text{hydrolytic}} = \frac{\text{constant of electrolytic dissociation for water}}{\text{constant of electrolytic dissociation for the base}}$$

From the concordance between the values of the two series of hydrolytic constants (and consequently also electrolytic constants) found by different ways, one cannot, however, in this case deduce the correctness of the hypothesis (electrolytical dissociation), since a hydrolytic constant calculated under the assumption of dissociation into components only is of about the same amount, and the single values show as much conformity as do K^I and K^{II}. I have calculated this series of constants from the experiments under 2 (conductivity) and put them down in the table under K^{III}.

3. The conductivity of dimethylpyrone in liquid SO₂ was examined. The molecular conductivity was found to increase with increasing dilution, a fact that suggests the formation of a salt.

4. The conductivity of dimethylpyrone and tribromoacetic acid separately and mixed together. Separately both showed a very small conductivity, together a considerably greater. But the molecular conductivity *decreased* with increasing dilution.

Obviously there are things in these investigations which may suggest the formation of a salt in the above-mentioned cases, but none of them offers a stringent proof.

It must, however, be possible to decide absolutely the question by measuring the concentrations of H ions and of Cl ions in an aqueous solution of dimethylpyronehydrochloride. If only dissociation into components:

takes place then the H ion concentration must be equal to the Cl ion concentration, as both kinds of ions then will originate only from the acid set free by the hydrolysis. The dimethylpyronehydrochloride will in this case be a molecular compound.

If the product is a salt, then the Cl ion concentration must be greater than the H ion concentration, for besides the Cl ions which originate from the free acid:

there must also be Cl ions originating from the salt:

The Cl ion concentration can be determined with sufficient accuracy by measuring the potential difference between the solution and a Hg/HgCl electrode. The determination of the H ion concentration by measuring the potential difference between the solution and a H electrode had to be given up, for it turned out by experiments I made that the dimethylpyrone was decomposed by the hydrogen. But the H ion concentration can be determined in other ways. The question is only to choose a method which affords the necessary accuracy. The colorimetric method will according to Sorensen¹ only allow an accuracy of ± 0.1 in the H ion exponent ($= -\log (\text{H}^+)$). In a 0.1 *N* solution the degree of hydrolytic dissociation of dimethylpyronehydrochloride is about 0.85 according to the experiments of Walden.

If the electrolytic dissociation of hydrochloric acid is estimated to be complete into a 0.1 *N* solution, then the question will be of the determination of the difference between two H ion exponents which in the highest can be:

$$\log 0.1 - \log 0.085 = 0.07.$$

In other words, the quantity that should be determined is of about the same amount as the uncertainty of the measurement. The colorimetric method is then unfit for use in this case. A more accurate method we have in measuring the catalysis of the saponification of diazoacetic ester, but this method is unsuitable in this case, as Bredig and Ripley² have shown that it cannot be employed when only a trace of Cl ion is present.

While the determination of the conductivity alone cannot solve the problem, as I have shown above, determinations of the conductivity combined with determinations of the Cl ion concentration will answer the purpose.

A solution of dimethylpyronehydrochloride and a solution of hydrochloric acid, whose Cl ion concentrations electrometrically measured are equal, will have the same conductivity, if the dimethylpyronehydrochloride is only dissociated into components. If, on the contrary, also electrolytic dissociation takes place, then the molar conductivity of the dimethylpyronehydrochloride solution will be smaller than the mol. conductivity of the hydrochloric acid solution, for the Cl ion concentrations are equal in both solutions, but in the pyrone solution a part of the fast-migrating H ions are replaced by the much slower migrating dimethylpyrone ions.

¹ "Ueber die Messung und Bedeutung der Wasserstoffjonenkonzentration bei biologischen Processen," S. 428.

² *Ber.*, 40, 4015.

This is seen most distinctly when the experimental results are plotted in a diagram. Plotting corresponding values of molecular conductivity against electrometrically measured Cl ion concentration the result will be one single curve common for the pyrone solution and the hydrochloric acid, if dissociation into components only takes place. In case of electrolytic dissociation of the non-hydrolyzed part two separate curves will result, the curve for hydrochloric acid lying higher than the other. They will unite at the point which gives the molecular conductivity of hydrochloric acid at ∞ dilution (Cl ion concentration = 0) and will separate more and more with increasing concentration.

Experimental.

Consequently my experiments included electrometric determination of Cl ion concentration and of conductivity. The solutions of dimethylpyronehydrochloride, which in the following I shall simply call D-solutions, were made by dissolving accurately weighed quantities of crystallized $C_7H_8O_2 \cdot HCl \cdot 2H_2O$.

The strength of the hydrochloric acid, of which I measured the conductivity and Cl ion concentration, was determined by adding a small excess of silver nitrate to 20 cm³. of the acid and reducing the precipitated AgCl in hydrogen. The result was

$$1.1932 \text{ g. Ag}$$

wherefrom the strength of the acid is found to be 0.4424 *N*. The other solutions were produced by dilution by means of an accurate pipet (Geissler).

To the determination of the Cl ion concentration four half-elements of the type:

were constructed for each dilution.

They were measured by the compensation method (Poggendorff) against a 0.1 *N* Hg, HgCl electrode, a 3.5 *N* KCl solution and a 1.75 *N* KCl solution being successively used to produce the contact between the two electrode solutions in order to eliminate the diffusion potential. During the measuring the elements were placed in a water-thermostat, the temperature of which did not alter more than 0.1°. Until the measurements were made, the syphon tubes of the electrodes dipped into small glasses holding the same solution as in the electrode spaces in order to prevent the concentration from altering by evaporation.

The results of the measurements are collected in the following Tables I and II. Under [Cl⁻] the Cl ion concentration calculated from the potential difference. By means of Nernst's equation:

$$\pi = \frac{RT}{0.4343e} \cdot \log \frac{c_1}{c_2},$$

which holds for the potential difference after the diffusion-potential has been eliminated, and where c_1 and c_2 mean the concentrations of Cl ions, respectively, in the D-solution (or the HCl solution) and in the 0.1 *N* KCl solution is found at 19.8°.

$$\log [\text{Cl}^-] = \frac{\pi}{0.0581} + \log 0.085.$$

The extrapolated potential and the Cl ion concentration is shown in Figs. 1 and 2 by the curves π and [Cl⁻]. Between the points the curve has been drawn by help of a flexible ruler whereby the \times -marked values of [Cl⁻] have been graphically corrected.

The conductivity of the D-solution was measured at 18.0° and at 19.0°; in Table III the values of Λ 19.8° marked with \times are directly measured, the others calculated by help of the temperature coefficient from the values under Λ 18.0°, which are all directly measured. For the hydrochloric acid the conductivity has been determined only at 19.8°. Between the points so determined the curve has been drawn in as good accordance as possible with the 18.0° curve, the values of which are taken from Kohlrausch and Holborn: "Leitfähigkeit der Elektrolyte."

Fig. 1.—D-solution.

Fig. 2.—Hydrochloric acid.

In Table IV the directly measured values are marked with x .

In Figs. 1 and 2 the conductivities are shown by the curves Λ ; the upper one holds for 19.8°, the lower one for 18.0°.

Finally corresponding values of Cl ion concentration and mol. conductivity are plotted together into Fig. 3, respectively, for D-solutions (curve Λ_D) and for hydrochloric acid (curve Λ_{HCl}). As deduced in the theoretical part the shape of these two resulting curves affords a stringent

Fig. 3.

proof that in aqueous solutions of dimethylpyronehydrochloride electrolytical dissociation of the non-hydrolyzed part of the addition compounds takes place, so that *dimethylpyronehydrochloride* is a real salt and consequently an atomistic compound.

Discussion of the Results.

The equation by means of which the Cl ion concentration has been calculated from the potential only holds for diluted solutions, as it is based upon the applicability of the gas laws upon the dissolved substance. Consequently only that part of the curves which corresponds to concentrations smaller than 0.1 N gives the exact values of the Cl ion concentration.

For the higher concentrations the method of calculation employed will not give the absolutely correct values of the Cl ion concentration. Still the values can very well be used for comparison, since we must take it for granted that the same Cl ion concentration will give the same potential difference against a Hg/HgCl electrode, even if the relation between these two quantities is not expressed by the Nernst equation.

The experimental error in the determination of the molecular conductivity is about $\pm 0.5\%$. The alterations which might arise in the viscosity or possibly in the dielectric constant of the solvent by the presence of dimethylpyrone have been estimated to be of no importance in this case. The experimental error in the determination of the potential difference arises mainly from the elimination of the diffusion potential. Even in concentrations below $0.1 N$ it ought to be estimated as at least ± 0.5 millivolt, which gives an error in $[Cl^-]$ of about $\pm 2\%$, but it can increase to double the amount, if special precautions are not taken. From the diagram it is evident that errors of this amount will not alter the shape or the reciprocal situation of the curves.

The determination of the potential difference is in itself uncertain for concentrations over $0.1 N$, for the elimination of the diffusion potential will here involve an increasing error, but at the same time the differences between the corresponding conductivities increase so strongly, as may be seen in Fig. 3, that the reciprocal situation of the curves doubtless is correct also for this part.

As the salt character of the addition compound has hereby been proved, the calculation of a base constant for dimethylpyrone is now legitimate. Walden¹ from his conductivity measurements of the picrate calculated:

$$K_b = 2.4 \times 10^{-14}$$

by means of Bredig's table over the range between the molecular conductivity of a salt at ∞ -dilution and the molecular conductivity at lesser degrees of dilution. He ascribed to the dimethylpyrone ion the velocity of migration: $35 =$ the velocity of migration of organic bases of similar constitution (tertiary, cyclic, containing 18 atoms).

Without help of Bredig's table² the dissociation constant can be calculated in the following way, when the Cl ion concentration is known both for D-solution and for HCl solutions.

By comparing the molecular conductivities of a D-solution and a HCl solution, both with the same Cl ion concentration, it is evident that the ratio of the difference δ between these two conductivities and the difference which would arise, if all H ion was linked under formation of dimethylpyrone ion is

¹ *Loc. cit.*

² *Z. physik. Chem.*, 13, 191 (1894).

$$= \frac{\delta}{\gamma(\Lambda_H - \Lambda_D)} = \text{the degree of association}$$

= 1 — the degree of hydrolysis. Then the degree of hydrolysis is:

$$\alpha = 1 - \frac{\delta}{\gamma(\Lambda_H - \Lambda_D)} = \frac{\gamma(\Lambda_H - \Lambda_D) - \delta}{\gamma(\Lambda_H - \Lambda_D)}$$

wherein Λ_H means the velocity of migration of H ion, Λ_D the velocity of migration of dimethylpyrone ion which, like Walden, I estimate to 35— γ is the degree of dissociation of the hydrochloric acid and it is supposed that a non-hydrolyzed dimethylpyronehydrochloride solution would have the same degree of dissociation, a supposition which can involve no remarkable error.

By this the following values are calculated:

Strength of the solution.	α .	Constant of hydrolysis.
0.100	0.88	0.63
0.0661	0.92	0.68
0.0250	0.96	0.59

Average, 0.63

from which the constant of dissociation for dimethylpyrone as a base is found:

$$K_b = 1.9 \times 10^{-14}$$

of about the same amount as the constant calculated by Walden.

After this there can be no serious doubt about the configuration formula of the dimethylpyronehydrochloride.

The configuration of dimethylpyrone itself is:

The possibilities for the formation of an addition compound with one molecule HCl, excluding the oxonium formula, are:

All of them have been discussed and some of them defended, but surely not one of them can account for electrolytic dissociation, so that the oxonium formula must be correct:

I am going to extend these investigations to the addition compounds of ethers with acids. The simple structure of the ethers will entail that the structure of the addition compounds is quite doubtless, if they turn out to be salts like dimethylpyronehydrochloride.

POLYTECHNICAL HIGH SCHOOL,
COPENHAGEN, DENMARK.

THE PRODUCTION OF CHLOROPICRIN BY THE ACTION OF AQUA REGIA ON ORGANIC COMPOUNDS.

[PRELIMINARY PAPER.]

BY RASIK LAL DATTA AND NIHAR RANJAN CHATTERJEE.

Received January 12, 1915.

Aqua regia has been found to be a chlorinating¹ as well as an oxidizing agent.² It has now been found that it sometimes acts destructively, leading to the rupture of organic substances subjected to its action, with the production of chloropicrin. The transformation into chloropicrin is quantitative in some cases, in others it takes place to a limited extent while in some cases it does not take place at all. The action of aqua regia on the following substances has been studied.

Acetone.—Aqua regia decomposes acetone almost quantitatively into chloropicrin and the reaction can therefore be employed as the best method

¹ Datta and Fernandes, *THIS JOURNAL*, 36, 1007 (1914).

² Datta, *Ibid.*, 36, 1011 (1914).

for the laboratory preparation of this substance. Hofmann¹ gave a laboratory method for the preparation of this compound by the action of bleaching powder on picric acid. This procedure, however, gives only poor yields and is troublesome to carry out.

To a mixture of 2 parts of nitric acid and 3 parts of hydrochloric acid, acetone is gradually added, the acid mixture being warmed slightly. An oil separates at first, which soon dissolves with the production of the characteristic odor of chloropicrin. The addition of acetone is stopped when a quantity equal to a tenth part of the acid mixture has been added. When the whole of the acetone has been added the mixture is warmed on the water bath for some time to enable the reaction to become complete. The resulting liquid is next subjected to steam distillation and the compound is separated, dried by means of calcium chloride and finally distilled at a slightly reduced pressure.

The substance boiled between 113–114° at about 750 mm. The yield obtained was 85% of the theory. To establish its identity a chlorine determination was made.

0.1661 gave 0.4288 AgCl. Calc. for CCl_3NO_2 : Cl, 64.74; found: 63.86.

It has been observed that if the reaction is carried out in the cold, with very gradual addition of acetone, an oil containing chloropicrin separates, which, on slow evaporation in a desiccator, yields colorless crystals having m. p. 103–104°. This is being investigated.

Allyl Alcohol.—The action of aqua regia on allyl alcohol was next studied, in as much as it contains an unsaturated bond. When the reaction was carried out with warming, quantitative production of chloropicrin was the result; but when it was carried out in the cold, a mixture of chloropicrin and another substance which is under investigation was produced. Allyl alcohol was gradually added to a mixture of the acids (2:3), with occasional warming on the water bath. Its transformation into chloropicrin was complete. The resulting solution was subjected to steam distillation. A colorless oil was obtained which was identified by distillation as usual.

Ether.—When ether was added in small portions to aqua regia no change was apparent at first, but on warming limited action took place. At the end of the reaction no oil was deposited, a pungent odor of chloropicrin being noticed as usual. The product was separated by steam distillation and it was found that a very small quantity of chloropicrin had been formed.

Ethyl Alcohol.—Ethyl alcohol is decomposed only partially with the formation of chloropicrin. To a mixture of nitric and hydrochloric acids (2.3), ethyl alcohol was added in small quantities. At first no reaction took place, but after a time the action became violent and the

¹ *Ann.*, 139, 111 (1866).

acid mixture had to be cooled. After the action had subsided the mixture was warmed on the water bath for a few minutes. The chloropicrin was recovered as usual after steam distillation.

Methyl Alcohol.—Methyl alcohol remains undecomposed by aqua regia even on warming on the water bath and hence no chloropicrin is produced. After a very prolonged action only a slight smell of chloropicrin could be noticed.

Formic and Acetic Acids.—These acids are quite stable and remain undecomposed even on warming. Consequently no chloropicrin is formed in these cases.

A host of other substances has been found to give chloropicrin as the ultimate decomposition product, and it appears that the production of chloropicrin might be quite general. Investigations to establish this as well as a general study of the action of aqua regia and also the action of nitric acid in conjunction with bromine and iodine on organic bodies are being continued.

CHEMICAL LABORATORY,
PRESIDENCY COLLEGE, CALCUTTA.

CONTRIBUTIONS TO THE KNOWLEDGE OF HALOGENATION. VII.¹ SUBSTITUTED NITROGEN CHLORIDES. THE ACTION OF CHLORINE ON CARBAMIC ESTERS AND BIURETS AND THE PREPARATION OF CHLOROCAR- BAMIC ESTERS AND CHLOROBIURETS.

BY RASIK LAL DATTA AND SATYARANJAN DAS GUPTA.

Received January 12, 1915.

The action of chlorine on ethyl carbamic ester has been studied by us² with the isolation of monochlorocarbamic ester. Schmidt³ obtained a condensation product of urethane with dichloroacetaldehyde, *viz.*, dichloro-ethylidene urethane by the action of the same reagent on the ester at a high temperature.

It has been found that the chloroderivatives of other esters of the series can be prepared by working with aqueous solutions of the urethanes in the cold. These have been specially isolated since they might serve as useful synthetic reagents on account of their greater stability than similarly substituted carbamide derivatives. It has been noted under monochlorocarbamic ester, that it readily serves for the chlorination of amines and amides which hitherto had to be chlorinated by means of alkaline

¹ Previous communications on the subject; see Datta, *J. Chem. Soc.*, 101, 166 (1912); Datta and Ghosh, *THIS JOURNAL*, 35, 1044 (1913); Datta and Gupta, *Ibid.*, 36, 386 (1914); Datta and Fernandes, *Ibid.*, 36, 1007 (1914); *Ibid.*, 36, 1011 (1914); Datta, *Ibid.*, 36, 1011 (1914).

² Datta and Gupta, *THIS JOURNAL*, 36, 386 (1914).

³ Schmidt, *J. prakt. Chem.*, [2] 24, 120 (1881).

hypochlorites. Besides, it has also been found that the monochloro-carbamic esters hydrolyze, giving rise to interesting condensation products. These compounds have been found to be extremely active, the chlorine in them being very loosely combined and they react vigorously with sodium. In fact these compounds promise to be of signal service in as mild chlorinating synthetic agents in the laboratory. The chloro-derivatives themselves are interesting since they represent a new class of substituted nitrogen chlorides which it has been our object to isolate. Besides the chloroderivatives of carbamic esters, the chloroderivatives of biuret and substituted biurets have been prepared.

It is very peculiar that no chloroderivative of the first ester of the series, *viz.*, methylcarbamic ester, could be prepared. It is, however, in keeping with the general notion that the first member of a homologous series behaves anomalously. The monochloroderivative of ethyl carbamic ester could be prepared by passing chlorine into a cold aqueous solution of the ester, as has been already described in a previous communication. In the case of ethylcarbamic ester, the monochloroderivative is the only product, however long the chlorination process is continued. But its next homolog behaves quite differently. Both monochloro- and dichloro-derivatives of propyl urethane could be obtained, although the latter could not be obtained pure, even when using chlorine in excess. The monochloroderivative could readily be prepared by passing a calculated quantity of chlorine into the aqueous solution of the urethane. Isobutyl carbamic ester can give rise to pure monochloroderivative although there is evidence of the formation of dichloroderivative, as is shown by the fact that the chlorine content approaches that of the dichloroderivative when chlorine is used in excess. In the case of the chlorination of isoamyl urethane, the monochloroderivative could not be prepared as an intermediate product, the dichloroderivative being formed at once.

Carbamic esters in which one or more amidic hydrogens are substituted, do not form the chloroderivatives at all. For instance, it has been found that chlorine has no action on chloral urethane. The action of chlorine on phenyl urethane is very peculiar, giving rise not to chloroderivatives, but to a complete condensation product. This might be accounted for by the fact that the phenyl radical, unlike the aliphatic radicals, easily takes part in condensation reactions. The action of chlorine on ethylidene ethyl carbamic ester is quite interesting. This breaks up during the chlorination process and dichloroethylcarbamic ester is the result, although the latter could not be prepared from ethyl carbamic ester itself under any conditions.

These compounds dissolve in almost all common organic solvents and are generally liquids of a pale yellow color. The boiling point, density and refractive index show a general regularity according to their increasing

molecular weights. The densities and refractive indices of the monochloroderivatives decrease while the boiling points increase with their increasing molecular weight.

The dichloroderivatives also show a similar behavior. On heating the liquids above their boiling points it was found that each had a temperature at which it decomposed with the separation of a solid product.

When these compounds are applied to the skin, a very painful sensation is produced and blisters are often formed which take considerable time to heal.

In the formation of these chloroderivatives substitution takes place with formation of hydrochloric acid, which remains dissolved in the mother liquor. As in other substituted nitrogen chlorides, the chlorine liberates iodine quantitatively from potassium iodide and this fact has been taken advantage of in analyzing these compounds.

Action of Chlorine on Methyl Carbamic Ester.

The action of chlorine on methyl urethane was studied under various conditions but in no case was it possible to isolate its corresponding chloroderivative. It appears that it is not capable of forming a chloroderivative.

Chlorine was first passed through a dilute solution of the ester, but even after passing it for a considerable time no sign of separation of the desired product was evident, although the peculiar smell belonging to this class of chloro compounds was perceived. It was thought that the great solubility of the chloroester might prevent its separation. To overcome this a saturated solution of methyl urethane was subjected to the prolonged action of chlorine, but in this case also, the solution only gave the peculiar smell due to chloroderivatives.

In order to determine whether the great solubility of the chloroderivative, together with the presence of the hydrochloric acid formed in the solution as a result of the reaction, prevented the reaction from proceeding beyond a limited extent the action of chlorine was next tried on the finely powdered urethane with only a few drops of water. The mass liquefied in a few minutes while the chlorine was passed into it. On examining the product, however, it was found that only a very small quantity of the substance was transformed into the chloroderivative. This causes the whole substance to liquefy and prevents further chlorination in accordance with the reason put forward above.

Finally it was decided to try the action of dry chlorine on the dry substance but no reaction took place. Nor was chlorination obtained when chlorine was passed into molten methyl urethane, the resulting product being unchanged methyl urethane.

Action of Chlorine on Propyl Urethane, Monochloropropylurethane, $\text{NHCl}-\text{CO}-\text{OC}_3\text{H}_7$.—The action of chlorine on propyl urethane results in formation of both monochloro- and dichloroderivatives, according as the

chlorination is stopped at an intermediate stage or carried to completion. An attempt was first made to prepare monochlorourethane by passing a rapid current of chlorine through a saturated aqueous solution of propyl urethane. Within a few minutes, a liquid began to separate. This was separated, dried and the halogen estimated. A much higher value than is required for the monochloroderivative was obtained. That the high percentage of chlorine was not due to chlorine dissolved in the liquid was shown by washing with water and dilute alkali which did not change the chlorine content. Hence, it was quite evident that the higher percentage of chlorine was due to the formation of some dichloroderivative. Since the liquid boils with decomposition, a separation could not be effected by distillation. Finally, the monochloroderivative was prepared by passing a calculated amount of chlorine into an aqueous solution of the substance, when the desired product separated as a pale yellow oil in the pure state.

0.2682 g. required 20.0 cc. 0.1 *N* thiosulfate; Cl as NaCl = 26.51.

0.2143 g. gave 0.2272 g. AgCl by Carius's method; Cl = 26.23.

0.1564 g. gave 0.1976 g. CO₂ and 0.0774 g. H₂O; C = 34.46; H = 5.49.

0.0974 g. gave 8.6 cc. N₂ at 30° and 760 mm.; N = 10.23.

Calc. for C₄H₉O₂NCl, C = 34.69; H = 5.83; N = 9.78; Cl = 25.82.

The substance is a pale yellow oil having, at 30°, a specific gravity of 1.269 and a refractive index of 1.45377. It is soluble in ether, methyl alcohol, ethyl alcohol, acetone, chloroform, carbon tetrachloride and benzene. With some of these solvents it is miscible in all proportions. Its action on the skin is a little less energetic than its lower homolog ethylchlorocarbamic ester. It takes a longer time for the first sensation of pain and the appearance of the blister on the skin. Its action on amines and acid amides is quite similar to that of its lower homolog. By its action both monochloro- and dichlorobenzylamines could be prepared from benzylamine, according as the one or the other be employed in excess. Benzamide was similarly chlorinated by means of it, with the production of the monochloroderivative.

Dichloropropylurethane, NCl₂—CO—OC₃H₇.—For the preparation of the dichloroderivative an excess of chlorine was passed through a well-cooled, saturated solution of the ester when it was obtained as a pale yellow mobile liquid. The product was washed and dried as usual.

0.2676 g. required 28.6 cc. 0.1 *N* thiosulfate; Cl as : NCl = 37.93; calc. for CC₃H₇NO₂Cl₂, Cl = 41.28.

As appears from the analysis above, the pure dichloroderivative could not be prepared. It is quite possible that during its formation in the presence of water, some of the monochloroderivative remains unchanged. Its properties are quite similar to the monochlorourethane as regards its solubility, action on amines and acid amides and action on the skin.

Monochloroisobutylurethane, $\text{NHCl}-\text{CO}-\text{OC}_4\text{H}_9$.—Like propylurethane, butyl urethane undergoes chlorination with the formation of both monochloro- and dichloroderivatives although the latter could not be prepared even in a state approaching purity. It is obtained as a mixture with the monochloroderivative. The monochloroderivative could be prepared similarly to monochloropropylurethane by passing a calculated amount of chlorine through a well-cooled aqueous solution of the urethane, when it separated as a pale yellow, mobile liquid having the characteristic odor of the chlorourethanes. It was washed and dried as usual.

0.1751 g. required 11.3 cc. 0.1 *N* thiosulfate; Cl as : $\text{NCl} = 22.84$. 0.2010 g. gave 0.1876 g. AgCl by Carius's method; $\text{Cl} = 23.09$. Calc. for $\text{NHClCO}-\text{OC}_4\text{H}_9$, $\text{Cl} = 23.44$.

The substance is a pale yellow, mobile liquid having a specific gravity of 1.156 and a refractive index of 1.44615 at 30° . The compound begins to boil with decomposition at 140° leaving off a white solid. At the same time white vapors are given out which condense on the upper and cooler parts of the tube. Its action on the skin is a little less energetic than its lower homolog and its behavior towards amines and acid amides is the same as that of its lower homologs, giving rise to chloroderivatives.

When a large excess of chlorine is used and the current is continued even after the separation of oil, there is a tendency for the formation of the dichloroderivative although it could not be obtained in a state of purity. It is obtained as a mixture of monochloro- and dichloroderivatives. In one experiment the percentage of chlorine went as high as 30.5%, the values calculated for monochloroderivative being 23.4 and that for the dichloroderivative 38.17%. As no method could be found to effect a separation the dichloroderivative could not be prepared in a pure state.

Dichloroisoamylurethane, $\text{NCl}_2-\text{CO}-\text{OC}_5\text{H}_{11}$.—The action of chlorine on isoamylcarbamic ester gives rise at once to the dichloroderivative and the monochloro product could not be obtained at all, even by stopping the chlorination process at an intermediate stage. For the preparation of the dichloroderivative a current of chlorine is passed into a quantity of powdered isoamylurethane suspended in water. The mother liquor, which at the beginning appears like a white emulsion, becomes quite clear after saturation with chlorine and the required product separates as a yellow oil. The oil was washed and dried as usual.

0.0957 g. required 9.45 cc. 0.1 *N* thiosulfate; Cl as : $\text{NCl} = 35.01$. Calc. for $\text{C}_5\text{H}_{11}\text{O}_2\text{NCl}_2$, $\text{Cl} = 35.5$.

The substance has a specific gravity of 1.156* and a refractive index of 1.45146 at 30° . It is soluble in ordinary solvents. Its action on the skin and on amines and acid amides is quite the same as that of its lower homologs. The compound begins to boil at 124° . At 145° dense white vapors arise from the surface of the liquid and the reaction is so vigorous

that it is accompanied by a sudden flash of light; at the same time a crystalline brown solid separates from the liquid.

Action of Chlorine on a Ethylideneurethane, Dichlorocarbamic Ester, $N-Cl_2.COOC_2H_5$.—The action of chlorine on ethylideneurethane is somewhat peculiar. It is a condensation product of acetaldehyde and ethyl urethane and it does not admit of chlorination before the rupture of the substance, and the rupture takes place with the formation of dichlorocarbamic ester, which could not be prepared by the direct action of chlorine on the ester as has been noted before.¹ Even by this method, the dichloroderivatives could not be prepared in a pure state being contaminated with a little monochloroderivative. The action which takes place may be explained thus: One atom of hydrogen directly united with nitrogen is

chlorinated first to form at $CH_3.CH \begin{cases} NCl.COOC_2H_5 \\ NCl.COOC_2H_5 \end{cases}$ but on further action of chlorine the compound breaks up into CH_3CHO and $NCl_2.COOC_2H_5$ thus:

For the preparation of the compound, ethylideneurethane was first powdered and suspended in water and then a rapid current of chlorine was passed through it. The solid gradually begins to change into oily globules which become more and more mobile and the whole of it finally changing into a mobile yellow oil when the action is complete. The liquid was separated from the mother liquor, washed and then dried. The yield amounted to about 60% of the theory.

0.1721 g. required 21 cc. 0.1 *N* thiosulfate; Cl as : $NCl_2 = 4.332$. Calc. for $NCl_2-COOC_2H_5$, Cl = 44.93.

The low percentage of chlorine in the product may be accounted for by the presence of monochloroderivative as impurity, from which it could not be separated.

It is a pale yellow, mobile liquid having at 30° a specific gravity of 1.304 and a refractive index of 1.45397. It has a smell similar to the ethylmonochlorocarbamic ester and affects the skin like the monochlorocarbamic ester. Its action on amines and acid amides is the same as has been found with the other members of the series, this being the most active among them. •

Action of Chlorine on Chloralurethane.—The action of chlorine on chloralurethane does not give rise to any chloroderivative. It appears that urethanes in which an amido group is substituted do not give chloro-

¹ *Loc. cit.*

derivatives unless they are decomposed into the original esters. In the case of ethylideneurethane it has been found that it decomposes into the original ester, the dichloroderivative of which is the result of the action of chlorine. But the stability of chlorourethane is considerable, owing to the electronegative character of the three chlorine atoms, and hence the compound remains unchanged on subjecting it to the action of chlorine under varying conditions.

Action of Chlorine on Phenylurethane.—The result of the action of chlorine on phenylurethane is quite interesting. Instead of giving rise to the usual chloroderivatives, a complex condensation product results. The first action might, no doubt, give rise to the usual chloroderivatives but the great reactivity of phenyl radical for substitution reactions might be the cause of the production of the condensation product.

A rather slow current of chlorine was passed through a quantity of phenylurethane suspended in water. At first a white emulsion came down which soon changed into a dirty gray, and then green, oily substance which afterwards turned to a pasty, brownish, solid mass. This was washed thoroughly with water and left to dry in a vacuum desiccator. The substance was first recrystallized from acetone and then again from ether. When crystals first form from an ethereal solution they appear perfectly white but after some time, and on keeping in a desiccator, they gradually turn to a very pale yellow color. On partially washing these crystals with successive small quantities of ether, white flakes of crystals remain behind. These crystals, on dissolving in alcohol and allowing to recrystallize undisturbed, give beautiful white needles. The substance had a sharp melting point of 83° . It is soluble in acetone, ether and alcohol. Its constitution could not be determined at present.

0.1321 g. gave 0.2102 g. CO_2 and 0.0520 H_2O , $\text{C} = 43.40$; $\text{H} = 4.00$. 0.1093 g. gave 7.8 cc. N_2 at 30° and 760 mm., $\text{N} = 8.10$. 0.1426 g. gave 0.0816 g. AgCl , $\text{Cl} = 14.16$. Calc. for $\text{C}_{18}\text{H}_{20}\text{N}_8\text{Cl}_2\text{O}_9$, $\text{C} = 43.72$; $\text{H} = 4.06$; $\text{N} = 8.50$; $\text{Cl} = 14.37$.

The Hydrolytic Product of Monochlorourethane.—It has been shown previously that monochlorourethane undergoes hydrolysis when kept in contact with water and alkalies for a time extending over several days in presence of air. The compound is completely decomposed and a white crystalline substance is formed below the water. The substance was recrystallized from alcohol and had a sharp melting point of 147° . Many preparations were undertaken with the same results. The compound corresponds to the formula $\text{C}_7\text{H}_{15}\text{N}_3\text{O}_4\text{Cl}$.

0.0940 g. gave 0.1188 CO_2 and 0.0528 H_2O , $\text{C} = 34.47$; $\text{H} = 6.18$. 0.1158 g. gave 17.00 cc. N_2 at 28.5° and 763 mm., $\text{N} = 17.20$. 0.0583 g. gave 0.0344 AgCl , $\text{Cl} = 14.50$. Calc. for $\text{C}_7\text{H}_{15}\text{N}_3\text{O}_4\text{Cl}$, $\text{C} = 34.92$; $\text{H} = 6.23$; $\text{N} = 17.46$; $\text{Cl} = 14.77$.

Its constitutional formula could not be assigned at present and further work is necessary to elucidate its constitution.

The hydrolytic products of the other chlorocarbamic esters are being studied and attempts are being made to apply them as synthetic agents.

The Action of Chlorine on Biuret and Substituted Biurets.

Having been successful in isolating the various chloroderivatives of the different carbamic esters, which are in fact substituted nitrogen chlorides, it was thought possible to substitute by chlorine the hydrogen atoms united to nitrogen in more complicated derivatives derived from carbamide in which the amido groups of urea remain intact, *viz.*, biuret and substituted biurets. From biurets, dichlorobiuret has been obtained, and acetylbiuret gave rise to dichloroacetylbiuret. These are important on account of the fact that they represent a new class of substituted nitrogen chlorides which have hitherto not been prepared.

Dichlorobiuret, $\text{NHCl}-\text{CO}-\text{NHCONHCl}$.—The action of chlorine on biuret gives rise to a dichloroderivative and there are three possible formulas for the same, *viz.*,

But on careful consideration and study of the other substituted nitrogen chlorides, it can be safely asserted that Formula I is the only possible one. The second formula can be rejected on the ground that both atoms of hydrogen of one of the NH_2 groups cannot be replaced when another symmetrically situated NH_2 group remains unacted upon. Formula III can also be rejected, owing to the improbability of substitution by chlorine in an imido group in preference to that in an amido group.

A few grams of biuret were taken in a flask with a quantity of water insufficient to dissolve the whole at the ordinary temperature. The water was next warmed to $60-70^\circ$ until all the biuret went into solution. When the solution had cooled somewhat, a rapid current of chlorine was passed through it when, within a very short time, a white precipitate began to form. This increased in quantity as the current of chlorine was continued. When it was found that the amount of precipitate no longer increased, the current of chlorine was stopped and the crystals obtained were filtered with suction and washed thoroughly with water. The substance thus obtained consisted of a crystalline white powder. It was then dissolved in alcohol and crystallized therefrom. The substance melted with decomposition at 160° with a sharp and sudden crackling sound.

0.1673 g. gave 0.8293 g. CO_2 and 0.0328 H_2O ; C = 13.52; H = 1.94. 0.0836 g. gave 17.8 cc. N_2 at 25° C. and 764 mm., N = 24.69. 0.1813 g. gave 0.3007 g. AgCl , Cl = 41.03. Calc. for $\text{C}_2\text{H}_3\text{O}_2\text{N}_3\text{Cl}_2$, C = 13.59; H = 1.74; N = 24.42; Cl = 41.28.

This substance, like the other substituted nitrogen chlorides, liberates

iodine from potassium iodide. Hence a volumetric estimation was undertaken in order to determine whether it agreed with the volumetric estimation given above. However, a certain anomaly was noticed which calls for a special explanation. The analysis was carried out by adding a weighed quantity of the biuret derivative to a solution of potassium iodide and then titrating the liberated iodine with sodium thiosulfate. The percentage of chlorine as the mean of several analyses was found to be 51.35%, whereas that obtained by gravimetric method was only 41.03. The chlorine calculated for trichlorobiuret is 51.55. The gravimetric estimation gives as a rule the whole of the chlorine of a substance if carried out in sealed tubes by the Carius method. Hence the excess of chlorine found by the volumetric method is certainly due to some decomposition reaction of dichlorobiuret itself which liberates an equivalent quantity of iodine from potassium iodide.¹

The action which takes place is one of substitution like the carbamides and carbamic esters, resulting in the liberation of hydrochloric acid which was found in the filtrate from the precipitated dichlorobiuret. The reaction is quantitative, unlike carbamide, since biuret is neutral and does not combine with hydrochloric acid, which therefore does not interfere with the chlorination.

The compound is quite stable, unlike the other substituted nitrogen chlorides which have a great tendency to decompose. A sample of the product was analyzed after being kept for nearly a month when all its chlorine was found intact although the substance could not be kept indefinitely. The compound was vigorously acted upon by a fairly strong solution of caustic potash but it dissolves to a yellow solution in a dilute solution of the same. It is fairly soluble in ether and insoluble in water and benzene.

Dichloroacetylbiuret, $\text{NHCO.CH}_3\text{—CO—NHCONCl}_2$. — Monoacetylbiuret was prepared according to the method of Schiff.² The monoacetylbiuret is dissolved in a small quantity of water by heating on the water bath to make a saturated solution. After cooling the solution to some extent, a rapid current of chlorine was passed into it when, within a few minutes, crystals began to appear. After passing chlorine for some time longer the solid was filtered off and washed with water in which it seemed to be slightly soluble. It is purified by crystallization from alcohol. The pure product melts with decomposition at 170° with a sharp crackling sound similar to that given by dichlorobiuret.

¹ The author has apparently overlooked the fact that compounds of the type of nitrogen trichloride liberate two atoms of iodine for each atom of chlorine present. See Hentschel, *Ber.*, 30, 1434. This is evidently because the chlorine is *positive* in these compounds. Noyes and Lyon, *THIS JOURNAL*, 23, 462 (1901); Noyes, *Ibid.*, 35, 767 (1913).—EDITOR.

² *Ann.*, 291, 377 (1896).

0.1380 g. required 13 cc. 0.1 *N* thiosulfate; Cl as : NCl = 33.31. 0.0933 g. gave 12.2 cc. N_2 at 29.8° and 763 mm., N = 19.80. 0.1701 g. gave 0.1387 g. CO_2 and 0.0379 g. H_2O , C = 22.24; H = 2.34. Calc. for $C_7H_5O_3N_3Cl$: C = 22.43; H = 2.34; N = 19.62; Cl = 33.31.

All attempts to prepare the chloroderivative of benzoylbiuret were unsuccessful. It appears that the increment of the acidic nature of the substance by a substitution of the benzoyl group has interfered with the formation of the chloroderivative.

The chloroderivative of other substituted biurets are in the course of preparation, as also other substituted nitrogen chlorides.

VIII. NEW SERIES OF CHLOROHYDROXY COMPOUNDS.

THE HYDROLYTIC CHLORINATION OF DIMETHYLPYRONE. THE ISOLATION OF 2,6-DICHLORO-HYDROXY-3,5-DICHLORO-4-KETOHEPTANE AND ITS DECOMPOSITION INTO 3,5-DICHLORO-2,4,6-TRIOXYHEPTANE.

By RASIK LAL DATTA AND SATYARANJAN DAS GUPTA.

Received January 12, 1915.

The chlorination of dimethylpyrone has been effected by a variety of reagents. Chlorine has been found quite satisfactory to effect the change, although potassium chlorate and hydrochloric acid and also aqua regia, which give chlorine in the nascent state, can effect the chlorination of dimethylpyrone with the taking up of a water molecule and the opening of the pyrone ring.

The action of barium hydrate on 2,6-dimethylpyrone¹ presents a close analogy to the case in question. When an aqueous solution of dimethylpyrone is boiled with baryta water, there separates an insoluble barium salt, containing four molecules of water of crystallization,

When this salt is dissolved in hydrochloric acid and the resulting solution is extracted with ether, diacetylacetone is formed. By the removal of barium as barium chloride, the hypothetical dihydroxy compound is first formed, thus:

¹ Feist, *Ann.*, 257, 276 (1890).

But according to Erlenmeyer's rule¹ free hydroxyl cannot exist as such, it rearranges itself, the oxygen of the hydroxyl unites doubly with carbon and, as a result of such molecular rearrangement, diacetylacetone or 2,4,6-triketoheptane is produced.

When dimethylpyrone is subjected to the action of chlorine, potassium chlorate and hydrochloric acid and also aqua regia, the compound becomes chlorinated, first four atoms of chlorine attach themselves to the two unsaturated double bonds and, secondly, the pyrone ring opens up, taking a water molecule thus:

Unlike the hydrolytic product from dimethylpyrone itself, the hydroxyl groups are on the doubly united carbon atoms, hence they remain as such, yielding a compound of a new type and remarkable interest. The compound so formed has been found to be 2,6-dichlorohydroxy-3,5-dichloro-4-ketoheptane. In this compound, a chlorine atom and a hydroxyl group are both united with the same carbon atom. The above compound is very unstable, as might be easily inferred from the nature of the groups attached. The attempts at preparing such types of compounds by direct chlorination of compounds containing hydroxyl group have hitherto been a failure, since there is a strong tendency for the splitting off of hydrochloric acid according to the following scheme:

But the formation of such a compound is possible in the case in question by the addition of chlorine atoms to the unsaturated bonds and the simultaneous taking up of water molecule without any side reaction.

As can be well anticipated from the nature of the groups attached,

¹ Ber., 13, 309 (1880); 25, 1781 (1892).

such a compound would readily lose hydrochloric acid and this has been found to be the case. When the compound, which is a fairly viscous oil, was kept in a stoppered bottle, its viscosity diminished in a few days and fumes of hydrochloric acid could be detected with ammonia vapor. The decomposed oil, on treatment with water, gives a white solid which has the formula $\text{CO}(\text{CHClCOCH}_3)_2$, which is 3,5-dichloro-2,4,6-triketohexane or dichlorodiacetylacetone and is formed from the original substance with the loss of two molecules of hydrochloric acid.

As by the direct hydrolysis of 2,6-dimethylpyrone we get diacetylacetone, so by the simultaneous chlorination and hydrolysis of 2,6-dimethylpyrone and subsequent hydrolysis of the resulting compound, dichlorodiacetylacetone has been prepared, which is a dichloroderivative of a triketone and it is interesting on account of the fact that similar chloroderivatives have not hitherto been prepared.

(1). **Preparation of 2,6-Dichlorohydroxy-3,5-dichloro-4-ketohexane.**

(a) **From Chlorine.**—When chlorine is passed to an aqueous solution of dimethylpyrone, the compound separates as a pale yellow oil which could be separated, washed and dried as usual. The yield obtained was nearly quantitative.

(b) **From Potassium Chlorate and Hydrochloric Acid.**—Potassium chlorate and hydrochloric acid acts primarily as a chlorinating and oxidizing reagent; but in this case it acts purely as a chlorinating agent. The best yield of the substance is obtained when the following directions are carried out: Dimethylpyrone is dissolved in an excess of dilute hydrochloric acid (1 : 1) and potassium chlorate in fine crystals is added in small quantities, when it dissolves without any evolution of gas. Repeated shaking with further quantities of potassium chlorate results in its solution, the solution turning yellowish. If the test tube be left to itself, the color appears after a considerable time but if briskly shaken it appears in about fifteen minutes. At the same time a peculiar odor is noticed. When more strong hydrochloric acid is added an immediate haziness is produced, which collects to a colorless oil. The direct precipitation of the oil points to the fact that it is insoluble in water in the presence of hydrochloric acid. After allowing the mixture to stand for some time the pale yellow oil which now collects at the bottom is separated by a separating funnel, washed with small quantities of water and dried by keeping in a desiccator.

The yield obtained is nearly theoretical.

Having no regard to the yield, the oil can be most rapidly prepared thus: Dimethylpyrone is dissolved in excess of strong hydrochloric acid (sp. gr.

1.16) and to it solid specks of potassium chlorate are gradually added with shaking, no second batch being added until the first batch dissolves. Turbidity results almost immediately and more and more of the oil collects. When no further turbidity is produced the addition of potassium chlorate is stopped. The oil can be separated and dried as usual.

(c) **From Aqua Regia.**—The action of aqua regia has been found to be destructive in almost all cases, except in the case of hydrocarbons, where it acts as a simple chlorinating agent¹ chiefly owing to the resisting power of the hydrocarbons. But it is very peculiar that this reagent acts simply as a chlorinating agent to form this substance which is so unstable. Dimethylpyrone is chlorinated quantitatively if the reaction is allowed to take place in the cold, whereas if the reaction be carried out at a slightly higher temperature, the product is a mixture of the chloroderivative and chloropicrin. Again, if the reaction is carried out at 100° pure chloropicrin, which is generally a product of the action of aqua regia on organic bodies, is produced.

For the preparation of the compound, dimethylpyrone in powder is gradually added to a mixture of nitric and hydrochloric acids, the latter being kept cold, preferably by immersion in cold water. Gradually the oil separates, increasing with continued addition of dimethylpyrone. The addition of dimethylpyrone is stopped when no more of the oil separates. The oil is next separated, washed and dried.

0.1824 g. gave 0.1908 g. CO₂ and 0.0417 g. H₂O, C = 28.52; H = 2.54. 0.0733 g. gave 0.1497 g. AgCl, Cl = 50.49. Calc. for C₇H₁₀O₃Cl₄, C = 29.58; H = 3.54; Cl = 50.00.

The substance is a pale yellow, moderately viscous oil which on heating first turns brown, then deep brown, finally leaving a black charred mass behind. The substance slowly decomposes on keeping, with the evolution of hydrochloric acid and a considerable diminution in the viscosity of the oil.

(2). Preparation of 3,5-Dichloro-2,4,6-triketoheptane.

A quantity of the oil which had been kept for some time in a stoppered bottle and whose viscosity had diminished considerably, was heated on the water bath for some time in order to remove any free hydrochloric acid which might be present. The halogen of the resulting oil was determined to ascertain its probable composition,

0.1458 g. gave 0.2914 g. AgCl, Cl = 48.56. Calc. for C₇H₁₀O₃Cl₄, Cl = 50.00.

The nearly equivalent chlorine content of this oil with that of the original oil led us to suspect that although the substance had decomposed into hydrochloric acid yet it might be in a mechanical mixture with the oil. In order to wash out the hydrochloric acid formed, the oil was repeatedly washed with water, when it became more and more viscous,

¹ Datta and Fernandes, THIS JOURNAL, 36, 1007 (1914).

finally showing signs of crystallization. The oil was left under water for some days to allow its crystallization to become complete. The substance was obtained in colorless crystals having a melting point of 145–146°. It was analyzed and was found to be 3,5-dichloro-2,4,6-triketoheptane.

0.1875 g. gave 0.2708 g. CO₂ and 0.0551 g. H₂O. C = 59.58; H = 3.40. 0.2331 g. gave 0.5187 mg. AgCl, Cl = 33.65. H = 3.79; Cl = 33.65.

Further investigations on similar lines are being continued.

**THE ACTION OF ACETIC ANHYDRIDE ON SOME BENZYLIDENE
ANTHRANILIC ACIDS. IV.**

By JOHN B. EKELEY AND CHARLES F. POE.

Received January 14, 1915.

Eighteen members of a series of acetketodihydrobenzmetoxazines have been described in previous papers.¹ These were obtained by the action of acetic anhydride upon the corresponding benzylidene anthranilic acids, according to the following reactions:

The previous members of this series, as described, were made by heating the benzylidene anthranilic acid with excess of acetic anhydride on the water bath for several hours, then evaporating off the excess of anhydride, and allowing the benzmetoxazine to crystallize out of the cooled concentrated solution. This method failed with certain benzylidene anthranilic acids, notably those derived from anisaldehyde and from piperonal, acetanthranilic acid being obtained instead of the expected benzmetoxazine. By a variation of the method, these benzmetoxazines have also been prepared. The benzylidene anthranilic acid was heated with molecular proportions of acetic anhydride in xylol solution for several hours, the excess of xylol was then distilled off, and the solution cooled in ice water. The benzmetoxazine derivative then crystallized out in a very

¹ THIS JOURNAL, 34, 161; 35, 282; 36, 604.

pure condition. The yield was much greater than had been obtained by the previous method of heating the two substances together without a solvent. Thus from 66 g. of benzylidene anthranilic acid 70 g. of phenylacetketodihydrobenzmetoxazine were obtained, whereas theory required 78 g. It was found, however, that in some cases the first method gives better results; for instance, in the case of salicylidene anthranilic acid, the latter method gives a syrupy mass from which it is difficult to obtain the benzmetoxazine, while by heating the benzylidene anthranilic acid directly with an excess of anhydride the benzmetoxazine is obtained easily and with a very satisfactory yield.

This paper will describe the benzylidene anthranilic acids obtained from *o*-toluylaldehyde, dibromosalicylaldehyde, 1,4- α -naphtholaldehyde, anisaldehyde, piperonal, methylvanillin, and *m*-methoxysalicylaldehyde, and the benzmetoxazine derivatives obtained from them.

In the condensation products from dibromosalicylaldehyde and from 1,4- α -naphtholaldehyde, it was found that the hydrogen of the hydroxyl group had been replaced by acetyl.

Experimental Part.

***o*-Toluylideneanthranilic Acid.**—Molecular amounts of *o*-toluylaldehyde and anthranilic acid in concentrated alcohol solution give a white, crystalline mass on standing, which may be recrystallized from a small amount of alcohol. Difficultly soluble in the ordinary organic solvents except methyl and ethyl alcohols, in which it is very soluble, and xylol. M. p. 143°.

Calc. for $C_{15}H_{13}O_2N$: N, 5.57; found: N, 5.6.

***o*-Methylphenylacetketodihydrobenzmetoxazine.** — *o*-Toluylideneanthranilic acid was heated with acetic anhydride in excess on the water bath for three hours. The excess acetic anhydride was then evaporated off, a stream of air being drawn over the liquid as it was being heated on the water bath. On cooling, the benzmetoxazine crystallized out. Recrystallized from alcohol it gave colorless prisms. Soluble in the ordinary organic solvents except ether. M. p. 166°.

Calc. for $C_{17}H_{15}O_2N$: N, 4.98; found: N, 4.9.

Dibromosalicylideneanthranilic Acid.—Dibromosalicylideneanthranilic acid separates out as a red crystalline mass when molecular amounts of dibromosalicylaldehyde and anthranilic acid are mixed in a cold alcohol solution. Recrystallized from alcohol, it yields scarlet needles, soluble in the ordinary organic solvents. M. p. 176°.

Calc. for $C_{14}H_9NBr_2$: N, 3.51; found: N, 3.22.

Acetyldibromophenylacetketodihydrobenzmetoxazine.—After heating dibromosalicylideneanthranilic acid with an excess of acetic anhydride and evaporating off the excess of anhydride as before, the benzmetoxazine

was obtained, mixed with a small amount of an intensely yellow crystalline substance, which probably is the unacetylated metoxazine. Colorless prisms, soluble in the ordinary organic solvents, except ether. M. p. 153°.

Calc. for $C_{18}H_{13}O_4NBr_2$: N, 2.89; found, N, 2.87.

Dibromophenylacetketodihydrobenzmetoxazine.—The yellow crystals remaining behind after heating the compound just described with alcohol were recrystallized from boiling xylol, giving yellow needles, insoluble in most organic solvents. M. p. 274°.

Calc. for $C_{16}H_{11}O_4NBr_2$: N, 3.22; found: N, 3.17.

1,4- α -Naphtholideneanthranilic Acid.—Molecular amounts of α -1,4-naphthaldehyde and anthranilic acid mixed in cold alcohol solution gave in a short time a maroon-colored mass. This was recrystallized from *warm* nitrobenzol, giving maroon-colored microscopic needles. Insoluble in the ordinary organic media, except acetone, methyl and ethyl alcohols. When boiled with nitrobenzol it decomposes partially. M. p. 195°.

Calc. for $C_{18}H_{13}O_3N$: N, 4.81; found: N, 5.04.

Acetyl - α - hydroxy - 1,4 - naphthoacetketodihydrobenzmetoxazine. — Heated on the water bath with excess acetic anhydride, 1,4- α -naphtholideneanthranilic acid yields the corresponding benzmetoxazine, the hydroxyl group being at the same time acetylated. Soluble in the ordinary organic solvents, difficultly in alcohol, from which it was recrystallized. Colorless microscopic needles. M. p. 238°.

Calc. for $C_{22}H_{17}O_5N$: N, 3.72; found, N, 3.57.

Anisylidenanthranilic Acid.—This was obtained as before by mixing a cold concentrated solution of anthranilic acid with anisaldehyde. The yellow crystals thus obtained were recrystallized from alcohol. Soluble in the ordinary organic solvents, except ether. M. p. 146°.

Calc. for $C_{15}H_{13}O_3N$: N, 5.49; found: N, 5.39.

***p* - Methoxyphenylacetketodihydrobenzmetoxazine.** — Molecular amounts of anisylidenanthranilic acid and acetic anhydride were heated for two and one half hours in xylol solution under reflux. The greater portion of the xylol was then distilled off and the remaining solution cooled in ice water. Sandy, colorless crystals separated out. These were filtered under suction, and, when washed with ether on the filter, were found to be snow-white in appearance. Soluble in the ordinary organic solvents except ether. M. p. 118°.

Calc. for $C_{17}H_{15}O_4N$: N, 4.70; found: N, 4.55.

Piperonalidenanthranilic Acid.—When molecular amounts of piperonal and anthranilic acid were brought together in cold alcohol solution, piperonalidenanthranilic acid separated out in a crystalline mass. Recrystallized from chloroform, it gave yellow crystals, soluble in the ordinary organic solvents except ether. M. p. 196°.

Calc. for $C_{15}H_{11}O_4N$: N, 5.20; found, N, 5.15.

3,4 - Methylenedihydroxyphenylacetketodihydrobenzmetoxazine. — Molecular amounts of piperonalideneanthranilic acid and acetic anhydride were heated together in xylol solution under reflux for two hours. The greater portion of the xylol was then distilled off and the remaining solution cooled in ice water. The solution separated into two layers, the lower one thick and syrupy. After standing several hours, this solidified into a mass of crystals. These were filtered under suction and washed with ether on the filter, yielding sandy, white crystals of the expected benzmetoxazine. Soluble in the ordinary organic solvents except ether. M. p. 126° .

Calc. for $C_{17}H_{13}O_5N$: N, 4.50; found: N, 4.31.

Methylvanillylideneanthranilic Acid.—Molecular amounts of methyl vanillin and anthranilic acid were brought into concentrated cold alcoholic solution. After standing over night, the methylvanillylidene anthranilic acid appeared as bright yellow needles. These, recrystallized from xylol, were soluble in the ordinary organic solvents except ether. M. p. 163° .

Calc. for $C_{16}H_{14}O_5N$: N, 4.91; found: N, 4.76.

3,4-Dimethoxyphenylacetketodihydrobenzmetoxazine.—As in the two preceding cases, the benzmetoxazine was obtained by heating molecular amounts of the acid and acetic anhydride in xylol solution under reflux, distilling off most of the xylol, and cooling the remaining solution in ice water. The oil which separated out in this case would not crystallize until a small amount of alcohol had been added, whereupon the expected benzmetoxazine separated out as white sandy crystals. These were filtered off under suction, and washed with ether on the filter. Soluble in the ordinary organic solvents, except ether. M. p. 106° .

Calc. for $C_{18}H_{17}O_5N$: N, 4.28; found: N, 3.99.

***m*-Methoxysalicylideneanthranilic Acid.**—This acid is formed when molecular quantities of *m*-methoxysalicylaldehyde and anthranilic acid are heated in xylol solution for several hours under reflux. On standing the solution deposits red needles. These were recrystallized from chloroform. Soluble in the ordinary organic solvents. M. p. 113° .

Calc. for $C_{16}H_{13}O_5N$: N, 5.16; found: N, 4.80.

Acetyl-2-hydroxy-4-methoxyphenylacetketodihydrobenzmetoxazine.—Molecular proportions of *m*-methoxysalicylideneanthranilic acid and acetic anhydride heated in xylol solution as in previous cases yield colorless crystals of the acetylated oxazine after the concentrated solution has stood in the cold for several days. These were recrystallized from xylol. M. p. 187° .

Calc. for $C_{19}H_{17}O_6N$: N, 3.97; found: N, 3.76.

3-Methoxy-4-acetoxypheylacetketodihydrobenzmetoxazine. — The preparation of the benzmetoxazine derived from vanillylideneanthranilic

acid and acetic anhydride by the method of heating the two substances in xylol under reflux gave a product which differed in its properties from that described in a previous paper¹ as made by the method of heating the acid and the acetic anhydride in excess. It is evident that the product previously described was not pure. To prepare the pure compound, it is necessary to heat the vanillylideneanthranilic acid with two molecular proportions of acetic anhydride in xylol solution under reflux for one hour. After distilling off the greater portion of the xylol, the acetylated metoxazine separates out on cooling in colorless sandy crystals. Recrystallized from xylol. Soluble in the ordinary organic solvents, except ether. M. p. 141°.

Calc. for $C_{19}H_{17}O_6N$: N, 3.97; found: N, 3.61.

THE ACTION OF FINELY DIVIDED SILVER ON α -BROMO- AND α -IODOPALMITIC ACIDS: SYNTHESIS OF TWO ISOMERIC DITETRADECYLSUCCINIC ACIDS.

By D. BREESE JONES.

Received January 12, 1915.

As is well known, the reaction between finely divided silver, so called "molecular silver", and monohalogen substitution products of the fatty acids is by no means a simple one. Besides the removal of halogen from two molecules of the substituted fatty acid and union taking place through the released affinities of the carbon atoms with formation of dibasic acids,

there are always formed several other products of the reaction. Hell and his co-workers have studied the action of silver on several halogen substituted fatty acids. From ethyl α -bromoisobutyrate and silver² were obtained two isomeric tetramethylsuccinic acids, carbon dioxide, ethyl bromide, isobutyric acid and methylacrylic acid, while ethyl α -bromobutyrate³ yielded ethyl bromide, ethyl alcohol, ethyl butyrate, two diethylsuccinic acids, and a sirup whose composition agrees with that of hydroxysuberic acid. Ethyl α -bromoisovalerianate with silver⁴ yielded two isomeric sebacic acids, ethyl bromide, ethyl isovalerianate, and

¹ THIS JOURNAL, 35, 164 (1913).

² Hell, *Ber.*, 10, 2229 (1877).

³ Hell and Mühlhäuser, *Ibid.*, 13, 473-9 (1880).

⁴ Hell and Mayer, *Ibid.*, 22, 48 (1888).

polymeric dimethylacrylic acids. Likewise ethyl α -bromopropionate¹ gave two dimethylsuccinic acids, ethyl propionate, ethyl acrylate and pyrocinchonic acid. In practically all cases two isomeric dialkylsuccinic acids were obtained.

It was accordingly deemed of interest to investigate the action of silver on halogen derivatives of higher fatty acids. In this article is described the action of silver on α -bromo-, and iodopalmitic acids. It was found that the halogen is readily removed from both bromo-, and iodopalmitic acid, either by heating alone with silver at a temperature of 130 to 140°, or by boiling the mixture in heptane. Among the products of the reaction, were obtained palmitic acid, an oil which showed properties of unsaturation, and the heretofore unknown two isomeric ditetradecylsuccinic acids.

Palmitic acid was invariably found as a product of the reaction. In one experiment with bromopalmitic acid, it comprised at least 20% of the original bromo acid taken, while in another experiment with iodopalmitic acid, 13% of the latter was converted into palmitic acid. This reduction of the original halogen acid probably takes place by abstraction of the halhydric acid, and subsequent reduction of the unsaturated acid.

The identification of the unsaturated acid, which is a constituent of the oily product which was always obtained, could not be determined, because of the small amount available to work with. Other unsaturated compounds than 1,2-hexadecylenic acid, might also well be present. Many olefines readily polymerize, with the formation of compounds which are still unsaturated. Hell and Mayer² obtained polymeric dimethylacrylic acid by action of silver on ethyl bromoisovalerianate. That an unsaturated dibasic acid of the type (I) may also be formed, is shown by the formation of pyrocinchonic acid (II) from bromopropionic acid and silver³

The two isomeric ditetradecylsuccinic acids obtained by action of silver on bromo-, and iodopalmitic acids, are characterized by difference in solubility and melting points. One melts at 135 to 136°, and is extremely difficultly soluble in most organic solvents, while the other melts at 95 to 96°, and is moderately soluble. When heated to about 170°,

¹ Hell and Rothberg, *Ber.*, **22**, 64 (1888).

² *Loc. cit.*

³ Hell and Rothberg, *Loc. cit.*

the acid melting at 135° loses water, and is converted into an anhydride melting at 45 to 45.5° , which on hydrolysis yields the acid melting at 95° . This latter acid, on the other hand, when heated to about 150° , also loses water and is converted into an unstable anhydride, which readily transforms into the same anhydride as that obtained by heating the higher melting acid. The acid melting at 135° was formed in much the larger amount of the two, although the yield was small. The maximum yield of this acid obtained from bromopalmitic acid was 8% of the amount calculated, while a maximum yield of 13% was obtained from iodopalmitic acid. The yield was better when the constituents were boiled in heptane, than when heated alone.

Practically all of the known symmetrically substituted dialkylsuccinic acids occur in two isomeric forms, which are characterized by a considerable difference in solubility and melting point. The nature of the isomerism has been long a question of speculation. These isomers have been commonly referred to as the "fumaroid" and "maleinoid" forms. According to van't Hoff's theory, these compounds having two asymmetric carbon atoms, would be naturally expected to occur in two inactive isomeric modifications, one inactive because of external, and the other inactive because of internal compensation, as in the case of *racemic*, and *meso* tartaric acids. Furthermore, on account of the many analogies they offer with the tartaric acids, their isomerism has frequently been referred to as of the same type. Accordingly, the fumaroid form, being the less soluble and having the higher melting point, was looked upon as having the *racemic*, and the maleinoid, as having the *meso* structure. However, this assumption was considered doubtful, as no one of the inactive dialkylsuccinic acids had ever been resolved into its active components, and not all of their properties fitted in with the analogy of the tartaric acids.¹ Bischoff,² to account for this isomerism, advanced a theory of *dynamical isomerism*, in which he considered the equilibrium positions of the atoms and radicals joined to the two asymmetric carbon atoms.

It is rather remarkable that it was not until 1913, that one of the inactive dialkylsuccinic acids was for the first time resolved into its optically active antipodes, when Werner and Basyrin³ succeeded in resolving one of the two inactive forms of dimethylsuccinic acid. Noyes and Kyriakides⁴ have also recently resolved into its optically active forms, one of the two inactive isomeric α, α' -dimethyladipic acids. It is very significant that in both of these cases, it was the more soluble acid, and the one having the lower melting point which was decomposed into the optically

¹ Auwers, *Ann.*, 309, 316 (1899).

² Bischoff, *Ber.*, 24, 1074, 1085.

³ Werner and Basyrin, *Ber.*, 46, 3229 (1913).

⁴ Noyes and Kyriakides, *THIS JOURNAL*, 32, 1057 (1910).

active components. It was found impossible to resolve the less soluble acid having the higher melting point. From this it appears that, unlike the tartaric acids, the racemic, or fumaroid form of the dialkylsuccinic acids are the varieties of the low, and not of the high melting points.

It is extremely probable, therefore, that of the two ditetradecylsuccinic acids described in this article, the less soluble one melting at 135 to 136° is the *meso*, while the more soluble acid melting at 95° is the *racemic* modification.

Experimental.

The palmitic acid, which was used in this work for the preparation of the bromo- and iodopalmitic acid, was obtained by saponification of palm oil with potassium hydroxide and decomposition of the resulting soap with hydrochloric acid. It was fractionally distilled at 35–45 mm. The fraction boiling at 240–250° after two recrystallizations from gasoline was practically pure. It melted at 61.5° to 62°.

α -Bromopalmitic acid was prepared according to Hell and Jordanoff's¹ method by adding dry bromine to a mixture of palmitic acid and red phosphorus. An excess of bromine (40 cc.), which had been previously dried with concentrated sulfuric acid, was slowly dropped onto a mixture of 75 g. of palmitic acid which was intimately mixed with 3.5 g. of red phosphorus. The reaction was carried on in the sunlight and at first was violent, the addition of every drop of bromine being attended with a flash. After most of the bromine had been added the mixture was heated on a boiling water bath until the fumes of hydrobromic acid had practically ceased. The excess of bromine was removed by drawing a current of air through the warm mixture for a few minutes. The reddish, oily product was then poured into about a liter of water, allowed to stand over night, extracted with petroleum ether, and the acid allowed to crystallize by spontaneous evaporation of the solvent. No marked reaction was observed when the oily product was poured into the cold water. (Hell records that a vigorous reaction with evolution of heat occurs at this stage.) After a few recrystallizations from petroleum ether or ligroin the bromopalmitic acid separates in clusters of prisms which melt at 53 to 53.5°. The yield of the purified acid was 40 g.

Iodopalmitic acid was prepared by boiling for three hours 95 g. of bromopalmitic acid, dissolved in 200 cc. of alcohol, with 70 g. of potassium iodide. After filtering off the potassium bromide, the straw-colored filtrate was evaporated nearly to dryness and the residue triturated several times with potassium iodide solution, to remove free iodine. The iodopalmitic acid crystallized from petroleum ether in glistening scales which melted at 60 to 61°. (Ponzio² gives 57°.) Obtained a yield of 90 g.

¹ Hell and Jordanoff, *Ber.*, 24, 938 (1891).

² Ponzio, *Chem. Zentr.*, 82, 1361 (1911).

Action of Silver on α -Bromopalmitic Acid.—Three g. of bromopalmitic acid, dissolved in 25 cc. of heptane, was boiled with 3.1 g. of finely divided silver for nine hours in a paraffin bath. The silver was prepared by reduction of silver chloride by glucose and sodium hydroxide, and then dried at 135 to 140°. Evidence of a reaction between the silver and bromopalmitic acid was apparent within half an hour, as indicated by a change in the color and texture of the silver residue. The temperature of the boiling mixture was about 115°. The silver residue was filtered from the hot solution, and the filtrate was evaporated on a water bath to a small volume of liquid which solidified on cooling. This was then warmed with several times its volume of petroleum ether, allowed to stand for a few minutes, and the portion which remained undissolved filtered off. This white substance, which amounted to 0.08 g., melted at 120–130° to a clear oil and decomposed at 165–170° with evolution of bubbles.

The silver residue which had been filtered off, was first washed with hot petroleum ether, then extracted with boiling alcohol, and the alcoholic extract evaporated to dryness. This residue was now warmed with petroleum ether to remove traces of soluble matter, and 0.12 g. of a hard, light-colored, pulverulent substance was filtered off, which melted at 131–133° to a clear oil and decomposed with gradual effervescence at 155–160°. Altogether, there was thus obtained of this high melting product, 0.2 g., or 8% of the theoretical yield calculated for ditetradecylsuccinic acid.

The original heptane filtrate, to which was added the petroleum ether washings of the silver residue, yielded on evaporation an oil, which on cooling partially solidified forming a pasty mixture. This was stirred with ice-cold petroleum ether and filtered. By this method, 0.9 g. of a crystalline substance was separated from the oily fraction. This substance is soluble in dilute alkalis, from which it can be reprecipitated by addition of acids. After two recrystallizations from dilute alcohol, it separated in fine needles which melted sharply at 62–63°. Some of this substance mixed with pure palmitic acid melting at 62.5°, caused no lowering of the melting point, showing it to be pure palmitic acid. There was obtained 0.6 g. of this acid, which is 20% of the bromopalmitic acid originally taken. The actual percentage of palmitic acid formed is doubtless considerably more, as some must have been lost during the purification.

The petroleum ether filtrate from the palmitic acid left on evaporation a straw-colored oil. The examination of this sirupy product of the reaction is described in a subsequent paragraph.

Action of Silver on α -Iodopalmitic Acid.—The action of silver on iodopalmitic acid was carried on under the same conditions as in the case of bromopalmitic acid. The results obtained were analogous, excepting that a larger yield of the high melting acid, and a smaller amount of palmitic

acid were obtained. In one experiment 13% of the calculated yield of the former was obtained, while 13.3% of the iodo acid was converted into palmitic acid. These results suggest that iodopalmitic acid has a less tendency than the bromo acid, to split off halhydric acid, with consequently a smaller reduction to palmitic acid, and a greater tendency to lose its halogen, with the formation of the high melting acid.

Sym-Ditetradecylsuccinic Acid (melting at $135-6^{\circ}$),

—All of the fractions of the high melting acid,

(melting at $130-133^{\circ}$), obtained from several preparations as described above, were united and dissolved in boiling alcohol. On standing there soon separated from the alcoholic solution hard granular nodules, which melted to a clear oil at $133-135^{\circ}$, and decomposed at $170-180^{\circ}$ with slow evolution of gas, leaving a clear, colorless oil. After one or two recrystallizations from alcohol, the substance was obtained in hard clusters, or rosetts, which melted sharply at $134-135^{\circ}$. It can also be crystallized from hot glacial acetic acid, in the form of fine, soft aggregates which, when dry, can readily be reduced to a fine, flour-like powder.

Calc. for $\text{C}_{28}\text{H}_{52}\text{O}_4$: C, 75.29; H, 12.16. Found: C, 74.93, 74.83; H, 12.07, 11.96.

It slowly dissolves in boiling dilute ammonium hydroxide, forming a slightly opalescent solution, which, when acidified with dilute hydrochloric acid, regenerates the free acid as a light flocculent precipitate, melting at $135-136^{\circ}$. This acid is characterized by being extremely difficultly soluble in most solvents. It is practically insoluble in water, chloroform, acetone, carbon tetrachloride, ether, petroleum ether, benzene and ethyl acetate. It is moderately soluble in hot, but very sparingly soluble in cold alcohol. It dissolves readily in hot glacial acetic acid, but separates out again almost quantitatively on cooling. On account of these properties some trouble was encountered in purifying it. It can be best purified by dissolving in warm dilute ammonium hydroxide, precipitating with dilute hydrochloric acid and recrystallizing, first from alcohol and then from acetic acid. Thus purified it melts at $135-136^{\circ}$, and decomposes with bubbling at $165-170^{\circ}$.

Action of Heat on the Above Acid. Formation of Ditetradecylsuccinic

Anhydride,

—The ditetradecylsuccinic acid, contained in a short test tube, was heated to 180° in a sulfuric acid bath, and maintained at that temperature until the formation of bubbles had largely subsided. The temperature was finally raised to about 200° , at which point the evolution of gas had entirely ceased. During the heating, which occupied about three-quarters of an hour, the substance was stirred

with a platinum wire. The thick, slightly yellow oil solidified on cooling, to a hard crystalline cake. Loss of water during the heating:

Subst., 0.492; loss of weight on heating, 0.018. Calc. for $C_{32}H_{60}O_4$: H_2O , 3.53. Found: 3.65.

The crude product melted at $42-43.5^\circ$. It was purified by dissolving it in ether, and then adding a little more than an equal volume of absolute alcohol. On cooling in ice water it separated in fine, white, asbestos-like needles, which melted sharply at $45-45.5^\circ$ to a clear oil.

Calc. for $C_{32}H_{60}O_3$: C, 78.05; H, 12.20. Found: C, 77.71; H, 12.07.

This anhydride is extremely soluble in ether and practically insoluble in cold alcohol and water.

Hydrolysis of the Above Anhydride and Its Conversion into a Ditetradecylsuccinic Acid Melting at 95° .—This anhydride is quite stable even toward boiling water. When warmed with water it melted, forming a clear layer of oil. Even after boiling for four or five minutes, the oil remained on the surface of the water apparently unchanged. On cooling the oil solidified, forming a crystalline crust which melted at 45° . The water remained perfectly clear, showing that not a trace of hydrolysis had occurred. The anhydride was accordingly boiled for about three-quarters of an hour with 75 cc. of potassium hydroxide (1%). It readily dissolved, forming a milky, or opalescent solution. After filtering and acidifying with dilute hydrochloric acid, a light flocculent precipitate separated. This was dissolved in a small amount of ether, and the solution placed in a freezing mixture of ice and salt. There soon separated a light flocculent precipitate. This substance melted at 95° , forming a slightly turbid oil which became clear at $96-97^\circ$. It decomposed at $145-150^\circ$ with evolution of bubbles.

Calc. for $C_{32}H_{62}O_4$: C, 75.29; H, 12.16. Found: C, 75.10; H, 12.34.

It readily dissolves in warm dilute ammonium hydroxide, and is reprecipitated when acidified with hydrochloric acid. This acid is characterized, in comparison with the acid melting at $135-136^\circ$, by a greater degree of solubility in most of the common organic solvents. It is rather sparingly soluble in cold alcohol, and is more soluble in warm ether than in warm alcohol. It will not separate, however, from an extremely concentrated alcoholic solution. It is difficultly soluble in petroleum ether. It can be crystallized from glacial acetic acid, from which it separates as a light precipitate which, when dry, can be readily reduced to a fine powder. Especially striking is the behavior of the oil obtained by heating the acid a few degrees above its point of decomposition. If the acid is decomposed in a capillary tube, the resulting oil does not solidify on standing for a short time at room temperature. But on sudden cooling, by plunging the capillary into ice water, it solidifies. As soon as it is removed from the ice water it again melts to a clear oil at room temperature. When this

oil, however, is now slightly warmed by merely holding between the fingers, it quickly solidifies and then melts at $43-45^{\circ}$. Owing to the very small amount of substance available, it was impossible to make a closer study of these remarkable changes. They suggest, however, the formation of a low melting, unstable anhydride of the acid melting at 95° , which easily changes into the same anhydride as that obtained by heating the higher melting acid.

The properties of the acid melting at 95° , and its composition as indicated by analysis, show it to be a ditetradecylsuccinic acid isomeric with the acid which melts at $135-136^{\circ}$. The analogy with dimethylsuccinic acid and α, α -dimethyladipic acid, in both of which cases the more soluble acid, and the one having the lower melting point of the two inactive isomeric forms, were resolved into the optically active antipodes,¹ indicates that this ditetradecylsuccinic acid just described is probably the *racemic*, while its isomer melting at $135-136^{\circ}$ is the *meso* modification.

Examination of the Sirupy Residues Obtained by the Action of Silver on Bromo- and Iodopalmitic Acid.—The sirupy residues, obtained by the action of silver on the halogen acids, were united and dissolved in aqueous potassium hydroxide (1%). The solution was just neutralized with dilute hydrochloric acid and a slight excess of barium chloride solution added. A copious precipitate formed. This product after standing *in vacuo* over sulfuric acid for several days had somewhat of a sticky, rubberlike consistency. It was extracted in a Soxhlet extractor with ether for several hours, whereupon a considerable portion of the substance went into solution. (See below for the ether-soluble portion.) The ether-insoluble portion, after drying, consisted of hard lumps which were ground in a mortar, and decomposed with dilute hydrochloric acid by heating on a water bath. An oil separated which on cooling solidified to a hard crust. This was broken up, washed several times with water, dried *in vacuo* over sulfuric acid, and extracted in a Soxhlet apparatus with petroleum ether. A grayish white residue remained undissolved in the capsule.

The petroleum-ether extract on evaporation yielded a white crystalline residue, which after one crystallization from ligroin, and another from alcohol, was identified as palmitic acid. It melted sharply at $62.5-63^{\circ}$.

The grayish white residue which remained undissolved by the petroleum ether, was dissolved in a small amount of alcohol. On standing, a substance separated in the form of light flocculent aggregates, which melted at $90-93^{\circ}$ to a thick, translucent liquid, gradually clearing and becoming a perfectly clear oil at 115° . It decomposed with bubbling at about 150° . Despite all attempts to further purify it, it could not be obtained to melt to a *clear oil* at a definite temperature. It is, however, identical in all other respects with the lower melting ditetradecylsuccinic acid, and

¹ Noves and Kvriakides, *Loc. cit.*; Werner and Basyrin, *Ibid.*

is undoubtedly the same acid, but containing a trace of some impurity which persistently clings to it.

The ether extract, obtained by extraction of the barium salts, yielded on spontaneous evaporation of the ether a straw-colored residue having the consistency of vaseline. This was decomposed by warming in a water bath with dilute hydrochloric acid, and the clear oil which separated, extracted with ether. By spontaneous evaporation of the ether, there was obtained a clear, yellow oil. This oil readily decolorizes bromine water, and is soluble in dilute alkalis, from which it is regenerated when acidified. It showed no tendency to crystallize until after standing for about three months, when a crystalline substance separated. The crystals were spread on a porous plate to remove the adhering oil, and then washed with a little cold alcohol, whereby the substance was obtained nearly white. After two recrystallizations from acetic acid, and another from ether in a freezing mixture, it melted at $86-90^{\circ}$ to a slightly turbid oil which became perfectly clear at 100° and decomposed with bubbling at about 150° . It dissolves easily in warm dilute ammonium hydroxide, and is reprecipitated in a flocculent form when acidified with hydrochloric acid. This substance shows all of the properties of the ditetradecylsuccinic acid which melts at 95° .

The oil from which the above acid was obtained showed strong properties of unsaturation. Unfortunately, the amount available was so small that further investigation of it was impossible.

THE CONSTITUTION OF ACETYLACETONE-THIOUREA.

By WILLIAM J. HALE AND ARTHUR G. WILLIAMS.

Received January 15, 1915.

The constitution of acetylacetone-urea has been shown by de Haan,¹ and again by one of us,² to accord primarily with the formula advanced by Evans³ and at the same time to exist in a tautomeric imino, or colorless form. The ordinary product was considered quinoid in structure and possessed a decided yellow color. The condensation of thiourea with acetylacetone is described by Evans⁴ as proceeding in exactly analogous manner to the condensation of urea with this diketone and yielding two distinct condensation products. From the properties of these two products it seemed that their exact structures might be open to question. de Haan has shown conclusively that the so-called diurimido-acetylacetone

¹ *Rec. trav. chim.*, **27**, 162 (1908).

² *THIS JOURNAL*, **36**, 104 (1914).

³ *J. prakt. Chem.*, [2] **48**, 489 (1893).

⁴ *Ibid.*, **48**, 503 (1893).

is a pyrimidine at base and not a chain product; in similar manner in a subsequent paper we shall attempt to account for the structure of the so-called dithiourimido-acetylacetone—one of these two condensation products just mentioned. The other product, called by Evans acetylacetone-thiourea, accords with this exact constitution and proceeds from a direct ring condensation between the ketone and thiourea:

The possibility of thiourea condensing in its pseudo form must also be considered. The product would accord with the metathiazine formula (III)

In the former case we might expect a third tautomer bearing a mercaptan group, and in the latter case this identical mercapto compound may easily be derived by the second possible manner of condensation. The possibility of such a result, however, is at once dismissed when it is recalled that acetylacetone-thiourea scarcely blackens moist mercuric oxide or basic lead acetate solution, even by prolonged boiling—a property not in keeping with the presence of a free mercaptan group. This distinct characteristic is almost indicative of Formula III where sulfur is held in the ring. The inference of, however, and the entire basis for such metathiazine structure, is overthrown by the ease with which the *n*-methyl ether of acetylacetone-thiourea gives up its sulfur to these mild desulfurizing agents. We are, therefore, brought to the conclusion that only Formulas I and II can be presented for consideration—structures similar in every respect to the two possible tautomeric formulas for acetylacetone-urea.

The free acetylacetone-thiourea is almost colorless when pure—a point in favor of the tautomeric imino form (II). However, when a thio group is present the absence of marked color cannot be taken as argument against the quinoid structure. In the application of Hinsberg's test for the presence of a secondary amine (or imino) group, only negative results could

be obtained; a result identical with that¹ obtained with acetylacetone-urea, which is known to exist in both keto and imino forms, and consequently due no doubt to the strongly negative thio group. The action of diazomethane upon this acetylacetone-thiourea, both in methyl alcohol and in chloroform solutions, failed to give any appreciable quantity of a methyl ether corresponding to that which was readily and quantitatively prepared when diazomethane acted upon acetylacetone-urea. This result was unexpected and can only be used as an argument against the imino form (II) for the free substance. The compound, therefore, may be regarded as existing primarily in its quinoid structure, namely, that of the 2,5-dihydro derivative (I): a 4,6-dimethyl-2-thio-2,5-dihydropyrimidine. The tendency toward formation of salts is to be looked upon, however, as proceeding from the imino form. The process was found slow and in nowise complete.

The preparation, not only of this *n*-methyl ether but also of the thio ether, was accomplished by condensation of acetylacetone with methyl thiourea, $\text{NH}_2\text{CS.NHCH}_3$, and on the other hand with methyl iminothiocarbamate, $\text{NH}_2\text{C(SCH}_3\text{):NH}$, respectively.

The condensation with methyl thiourea proceeded readily in acid solution:

The free substance, melting at 156.5° , is colorless and is easily blackened by warming with mild desulfurizing agents. The resistance of the sulfur in acetylacetone-thiourea to these same agents is therefore no longer apparent when one of the nitrogen atoms carries a substituent. The complete desulfurization of the ether, and replacement of sulfur by oxygen, was accomplished by several hours' boiling with an aqueous solution of chloroacetic acid. The product hereby obtained is naturally identical with that product prepared by the condensation of acetylacetone and methylurea.² The structure (IV) therefore of the ether of acetylacetone-thiourea is established. The desulfurization of acetylacetone-thiourea itself by means of chloroacetic acid was found to give acetylacetone-urea as expected.

Condensation of acetylacetone with methyl iminothiocarbamate, *i. e.*, pseudomethyl-thiourea, proceeded well in alkaline solution:

¹ THIS JOURNAL, 36, 113 (1914).

² *Ibid.*, 36, 114 (1914).

The oil separating out is somewhat difficult to purify, but the free product obtained by distillation *in vacuo* agreed in all respects with the thio ether (m. p. 24°) prepared by Wheeler and Jamieson.¹ We started with the product which Dixon² made by the action of thiourea upon methyl chloro-carbonate. Upon melting this methyl pseudo-thioallophanate, we secured the pseudomethyl-thiourea in the form of its hydrochloride. Wheeler and Jamieson condensed the methyl iodide addition product of thiourea with acetylacetone in the presence of alkali. The structure of their addition product, as investigated by Bernthsen and Klinger³ and by Werner⁴ and others, corresponds with that of a methyl ether of iminothiocarbamic acid in the form of its hydrogen iodide salt and consequently should enter into the condensation in the same manner as the hydrochloride salt employed by us. Furthermore, this thioether or 2-methylmercapto-4,6-dimethylpyrimidine, may best be prepared directly from free acetylacetone-thiourea by methylation with methyl iodide and sodium methylate. No matter by which of these three possible methods the methyl mercapto derivative is prepared, it is slowly transformed into the corresponding keto derivative, with consequent loss of mercaptan, when boiled for several hours with concentrated hydrobromic acid. This keto derivative is again the free acetylacetone-urea melting at 210°. Its production from acetylacetone-thiourea directly or through the intermediate step of a methylmercapto derivative, taken together with its corresponding production in the form of a methyl ether of acetylacetone-urea by the action of chloroacetic acid upon the methyl ether of acetylacetone-thiourea leave no room for doubt upon the constitution of the thiourea condensation product. The free acetylacetone-thiourea therefore may be looked upon as of the quinoid type (I) in equilibrium with a small proportion of the rather inactive imino type (II).

Experimental Part.

Acetylacetone-thiourea (I).—The method employed by Evans was found satisfactory in every respect. Two grams of thiourea were dissolved in 40 cc. of alcohol, 2 g. of acetylacetone then added and during cooling 50

¹ *Am. Chem. J.*, **32**, 356 (1904).

² *J. Chem. Soc.*, **83**, 566 (1903).

³ *Ber.*, **11**, 492 (1878).

⁴ *J. Chem. Soc.*, **57**, 283 (1890).

drops of concentrated sulfuric acid admitted to flask. After a day or two the yellow crystalline mass was filtered off and taken up in water. To this solution freshly precipitated barium carbonate was added to neutral reaction. The clear filtrate from the barium salts was then evaporated to dryness upon steam bath and this mass extracted with absolute alcohol. Upon further evaporation of the clear alcoholic solution to small volume the light yellow colored prisms of acetylacetone-thiourea make their appearance. The pure substance melts at 210° (uncor.). This compound is readily soluble in water or chloroform, from which latter it may be precipitated by ligroin in small colorless crystals; it is fairly soluble in alcohol, crystallizing best from this solvent; it is slightly soluble in benzene, ethylacetate, acetone or ether and insoluble in ligroin. It forms insoluble salts with metal ions of barium, silver and mercury as has been noted by Evans. The preparation of this acetylacetone-thiourea as a hydrochloride, using concentrated hydrochloric acid as a condensing agent, is also described by Evans, but the method was not found as practical as that where sulfuric acid is used.

Complete desulfurization of acetylacetone-thiourea was accomplished by the method of Wheeler and Liddle.¹ Two grams of the substance in solution with 15 cc. of water containing 2 g. of chloroacetic acid were boiled under a reflux condenser for a period of 4 or 5 hours. The mixture was then evaporated upon a steam bath and the residue treated with 90% alcohol. The part remaining undissolved was colorless. This colorless hydrochloride was next dissolved in a little water and the solution almost neutralized with alkali, when it was again evaporated to dryness upon the steam bath. The solid mass was now extracted with benzene to remove the free base. This latter came out of the concentrated benzene solution in colorless prisms melting at 198° and proved to be identical in all respects with the acetylacetone-urea of Evans. The two melted separately, and also when mixed, at this constant point.

Condensation of Acetylacetone with Methyl Thiourea.—One gram methyl thiourea and 1 g. acetylacetone in 10 cc. of alcohol are treated with 20 drops of conc. hydrochloric acid, and the yellow solution allowed to stand. The beautiful yellow prisms of the hydrochloride separate out over night. The hydrochloride was crystallized from alcohol for analysis.

0.2038 g. air-dried salt gave 0.1525 g. AgCl. Calc. for $C_7H_{10}N_2S.HCl$: HCl, 19.13%. Found: HCl, 19.04%.

The free substance—the 3,4,6-trimethyl-2-thio-2,3-dihydro pyrimidine, (IV), may be obtained directly from the hydrochloride by adding alkali to its aqueous solution and extracting this neutral mixture with chloroform. If the original reaction-mixture, before removing the hydrochloride, is allowed to evaporate spontaneously to dryness, and then its aqueous

¹ *Am. Chem. J.*, 40, 549 (1908).

solution neutralized with alkali and extracted with chloroform, practically a quantitative yield of the methyl ether is obtained; any methyl thiourea unacted upon will remain undissolved by the chloroform. This colorless methyl ether is insoluble in ligroin or ether; readily soluble in water, chloroform, acetone or alcohol, crystallizing from concentrated solutions in ether; and fairly soluble in ethyl acetate or benzene. It is best purified by crystallization from the latter, giving small needles melting at 156.5° . Prolonged boiling with concentrated hydrochloric is without action upon this product. This therefore verifies its structure as a *n*-methyl ether. By gentle warming with basic lead acetate solution, moist mercuric oxide or ammoniacal silver nitrate, a blackening or sulfide formation is observed.

0.1296 g. subs. gave 22.5 cc. N_2 (26° , 729.1 mm. over H_2O). Calc. for $C_7H_{10}N_2S$: N, 18.19%. Found: 18.36%.

One gram of this ether was dissolved in 15 cc. water containing 1 g. of chloroacetic acid and the mixture boiled in flask under reflux condenser for 3 hours. The contents of the flask were then neutralized with NaOH and extracted with chloroform. The chloroform extract, upon evaporation gave a low melting product which, when recrystallized from benzene, melted at 63° and corresponded in all other characteristics with the methyl ether of acetylacetone-urea (m. p. 63°) described by one of us in a previous paper.

Condensation of Acetylacetone with Pseudomethyl-thiourea.—The preparation of pseudomethyl-thiourea was in exact accord with the method described by Dixon.¹ Methyl chlorocarbonate was allowed to condense with thiourea and the crystalline product heated upon a water bath till the evolution of carbon dioxide had ceased and the hydrochloride of pseudomethyl-thiourea remained as residue. Attempts to condense this pseudomethyl-thiourea with acetylacetone in the presence of acids as condensing agents did not give good results. The tendency for desulfurization is apparent when free acids are present. In the presence of alkali, however, the condensation runs smoothly though here also decomposition into cyanamide has been noted. Five grams acetylacetone were added to a cold aqueous solution of 5 g. pseudomethyl-thiourea hydrochloride in 25 cc. of water containing also 2.5 g. of potassium hydroxide. The clear solution was allowed to stand one day, when an oil was found to have separated. This oil, shaken out with ether, dried over solid potassium hydroxide, and distilled *in vacuo*, gave a small quantity of distillate solidifying when cold to a colorless crystalline substance melting at 24° . This was found identical with the 2-methylmercapto-4,6-dimethylpyrimidine (V) (m. p. 24°) obtained by Wheeler and Jamieson¹ when acetylacetone was condensed in alkaline solution with the methyl iodide addition product by thiourea. Just as the product prepared according to the method of

¹ *Loc. cit.*

Wheeler, so also this product from our preparation was submitted to the action of concentrated hydrobromic acid for 3 to 4 hours under a reflux condenser. Mercaptan was copiously liberated and the contents of flask finally evaporated to dryness upon a steam bath. The residue taken up in water was just neutralized with alkali and again reduced to dryness upon steam bath. From this final residue, by extraction with benzene, a product is obtained which upon crystallization from alcohol melts at 198° and is identical with Evans acetylacetone-urea. The methylmercaptan therefore had been transformed into the corresponding keto derivative.

Methylation of Acetylacetone-Thiourea.—The addition of alkyl haloids to the free sulfur atom of acetylacetone-thiourea, just as with thiourea itself, is naturally to be expected. By the action of sodium methylate upon this addition product, which was made but not analyzed, we should expect to obtain the methyl thio ether or methylmercapto derivative of our pyrimidine. 0.6 g. of sodium was dissolved in 10 cc. methyl alcohol and 3.5 g. of acetylacetone-thiourea added. Into this solution 3.5 g. of methyl iodide (which must not be in excess of calculated quantity) in a few cc. of methyl alcohol were then admitted to the flask and the mixture warmed gently under a reflux condenser (over water bath) till neutral reaction appeared. The methyl alcohol was now removed by evaporation and the residue extracted with ether. The ether removed an excellent yield of the almost pure crystalline 2-methylmercapto-4,6-dimethylpyrimidine melting at 24° . When this latter was treated with concentrated hydrobromic acid, as before described, a quantitative yield of the acetylacetone-urea (198°) was obtained. The methylation, therefore, of acetylacetone-thiourea in its methylmercapto form is readily accomplished through the intermediate step of its alkyl halide addition product.

In attempting to methylate acetylacetone-thiourea by means of diazomethane, as was readily accomplished with acetylacetone-urea,¹ no positive results could be obtained. Methyl alcohol and chloroform also were used as solvents. From both solutions the greater part of acetylacetone-thiourea was recovered. In one or two instances it seemed that traces of both the thio ether and the imino ether were present but confirmatory tests were lacking. We are led therefore to the conclusion that acetylacetone-thiourea functions primarily as a quinoid base. The formation of thio ethers is only possible through the preliminary addition of an alkyl salt and consequently all tests to show the possible tautomerization for existence of mercapto group in this free base must have failed. The imino form then must be considered the normal tautomer and in reactivity placed far below the corresponding imino form of acetylacetone-urea.

ANN ARBOR, MICH.

ON THE DETERMINATION OF SMALL QUANTITIES
OF HYDROCYANIC ACID.

BY ARNO VIEHÖVER AND CARL O. JOHNS.

Received January 6, 1915.

In our work on cyanogenetic plants we found it necessary to estimate small quantities of hydrocyanic acid. The various titration methods as well as the silver gravimetric methods had to be excluded because we were working with plant distillates which usually contain reducing compounds. Furthermore, the quantities to be determined were often too small to permit the use of the above methods. We frequently had to deal with less than 0.5 mg. of hydrocyanic acid. Chapman¹ has shown that the picric acid colorimetric method of Waller² is not applicable to plant distillates which usually contain reducing substances other than hydrocyanic acid. This left two colorimetric methods to be examined, namely, the thiocyanate method and the Prussian blue method.

In the thiocyanate method of Francis and Connell³ the hydrocyanic acid is distilled into a solution of potassium hydroxide, yellow ammonium sulfide is added and the solution is evaporated to dryness. The residue is dissolved in water, acidified with hydrochloric acid and the mixture is filtered to remove sulfur, after which the filtrate is further acidified and boiled to cause precipitation of the free sulfur. The process of boiling and filtering is repeated until all of the sulfur has been removed from the filtrate. Ferric chloride is then added to the filtrate and the color of ferric thiocyanate is obtained. After an examination of this method we found that it was not accurate enough for our work. Our two chief objections to this method are as follows:

In boiling an acid solution of a thiocyanate, some free thiocyanic acid is lost because it is volatile, the boiling point of the acid being 85°. This loss was shown by taking two equal quantities of potassium thiocyanate, diluting both portions with water, acidifying with hydrochloric acid and boiling one of them for ten minutes in an Erlenmeyer flask. The boiled solution was then cooled. Both the boiled and unboiled portions were tested by adding equal quantities of ferric chloride. The portion that had been boiled gave less color than the one not boiled. This test was repeated and we found that in every case boiling resulted in a loss of thiocyanic acid.

The second important objection to the thiocyanate method is based on the nature of the reaction between a thiocyanate and ferric chloride, $\text{FeCl}_3 + 3\text{KCNS} \rightleftharpoons \text{Fe}(\text{CNS})_3 + 3\text{KCl}$. The equilibrium of this reaction is so easily disturbed by the addition of ferric chloride, intensifying the color, or the addition of other salts, diminishing this color, that it is

³ *THIS JOURNAL*, 35, 1624 (1913).

difficult to adjust conditions so as to obtain constant results. Changes of temperature also have a marked influence on the density of the color.

In recent years several papers have been published on the formation of Prussian blue from cyanides and the colorimetric estimation of the cyanide by comparison with a standard suspension of Prussian blue. The most careful attempts to arrive at a quantitative method seem to have been made by Berl and Delpy and by Lander and Walden.

Berl and Delpy¹ make the solution to be tested alkaline with potassium hydroxide, add a solution of ferrous sulfate, allow the mixture to stand at room temperature for at least ten minutes, shaking frequently, and finally boil for two to fifteen minutes. The resulting mixture is cooled and then acidified with hydrochloric acid. In the case of very dilute solutions of hydrocyanic acid, Berl and Delpy shake out the acidified solution with ether eight to ten times, and shake out the ether with a small quantity of potassium hydroxide solution, thus obtaining the hydrocyanic acid in a more concentrated form.

The method of Berl and Delpy has been improved by Lander and Walden.² These workers concentrate dilute alkaline solutions of hydrocyanic acid by boiling, the final concentrating being carried out in a test tube almost to dryness. The small quantity of liquid left is then cooled and ferrous sulfate solution added. The mixture is allowed to stand ten minutes, with frequent shaking, then acidified with hydrochloric acid and warmed gently.

Vorländer³ investigated the formation of Prussian blue from cyanides. He adds a solution of ferrous sulfate to the alkaline solution of the cyanide and boils for one to two minutes. He then filters and acidifies the filtrate with hydrochloric acid, after which he adds a cold, freshly prepared, saturated solution of ferrous sulfate. He allows the mixture to stand until the maximum color is obtained.

Knight⁴ adds to the alkaline distillate containing hydrocyanic acid, solid ferrous sulfate, then a solution of ferric chloride and boils for one minute. Hydrochloric acid in excess is then added to the hot solution. The precipitate of Prussian blue is filtered, washed with alcohol, and dissolved in a sufficient quantity of sodium hydroxide solution. This solution is acidified with acetic and hydrochloric acids, ferric chloride is then added and any brown color is removed by adding more hydrochloric acid. The mixture is concentrated to about one-half the original volume and the precipitate of Prussian blue, after filtration, is determined by weighing.

³ *Ber.*, 46, 181 (1913).

⁴ *J. Ind. Eng. Chem.*, 6, 909 (1914).

In a method involving the quantitative estimation of a substance by means of colorimetry, it is obvious that a given quantity of the substance should always produce a given density of color in a given volume of solution. It is also necessary that the shade of color should always be the same. For instance, a blue solution cannot be compared accurately with a blue-green solution. Our aim in this work has been to obtain a constant shade as well as density of color. We have studied the following conditions which influence the formation of Prussian blue and the shade of the suspension.

Influence of Concentration on the Formation of Prussian Blue.

Berl and Delpy found that they obtained less Prussian blue from given quantities of hydrocyanic acid in a dilute than in a concentrated solution. These authors, therefore, concentrated dilute solutions of hydrocyanic acid by shaking out with ether as previously mentioned. They state that in this manner nearly all of the hydrocyanic acid can be obtained. In our attempts to concentrate the hydrocyanic acid by means of ether, we found that we could not obtain nearly quantitative results. These low results are due partly to the loss of hydrocyanic acid which will occur by evaporation of the ether. This evaporation cannot be prevented at room temperature, since the acid solution has to be shaken out eight to ten times with ether. Moreover, the volume of alkali needed to extract the hydrocyanic acid from the ether will be so great that the maximum quantity of Prussian blue can scarcely be expected, as shown below.

Lander and Walden, finding also less precipitate of Prussian blue in dilute than in concentrated solutions of hydrocyanic acid, boiled the alkaline solution down almost to dryness. They state that this could be done without the loss of hydrocyanic acid.

The influence of concentration is indeed a very important factor. We made a series of experiments, using 1 mg. of potassium cyanide in each case and concentrations ranging from less than 1 cc. to 10 cc. In a dilution of 10 cc. less than one-half as much Prussian blue was obtained as when the volume was only 1 cc. We found that the maximum color was obtained only when the volume of solution to be tested was not greater than 1.5 cc., while in greater volumes the density of the color decreased with the increasing volume. Where the quantity of potassium cyanide was more than 1 mg. the volume of the solution to be tested could be somewhat increased without loss.

Hence, working with the methods of Berl and Delpy or Knight, where larger volumes than those mentioned above are used, the maximum quantity of Prussian blue would not be obtained.

To test the method of concentrating used by Lander and Walden, we evaporated 25 cc. of an alkaline solution of a cyanide to 1 cc. in a distilling flask and lost almost one-third of the cyanide. When the final evapora-

tion was performed in a test tube the loss was less but still considerable. Hence, it appears that the method of Lander and Walden also cannot give the maximum quantity of Prussian blue, since these authors evaporate over a free flame. It may be mentioned in this connection that evaporation in an open dish on a steam bath resulted in still greater losses than those mentioned above.

After numerous failures we found that alkaline solutions of hydrocyanic acid can be concentrated without appreciable loss by distilling under diminished pressure, as described below.

Influence of Salts on the Formation and Precipitation of Prussian Blue.

Vorländer states that the presence of salts delays or prevents the formation of Prussian blue. We tried the addition of salts, because in our early experiments we often obtained what seemed to be a colloidal form of Prussian blue. Since salts are known to precipitate colloids we tried the effect of adding sodium chloride and found that a clearer blue color was obtained than without the addition of this salt. We also tried the effect of several other halogen salts. Finally, we found that the presence of potassium fluoride had a remarkable effect on the formation and color of the Prussian blue. On acidifying in the final stage of the test the color appears at once and is very brilliant. The absence of a green shade makes it particularly suitable for comparison with a standard. If the acid is added very gradually the iron hydroxides dissolve and a colorless liquid with a white precipitate is obtained. On the addition of more acid the blue color appears. This is explained by the fact that ferric salts produce a complex salt with potassium fluoride,¹ K_3FeF_6 . When an excess of acid is added this complex salt is decomposed and the ferric ions needed for the formation of Prussian blue are furnished. Contrary to the statement of Vorländer, our experiments show that certain salts, such as sodium chloride and particularly potassium fluoride, hasten the formation of Prussian blue.

Influence of Acids on the Formation of Prussian Blue and on the Color of the Suspension.

Previous workers all seem to have used hydrochloric acid in the final stage of the test for a cyanide to precipitate the Prussian blue. We found that an excess of this acid tends to make the color of the suspension green, owing to the formation of ferric chloride. The mixture of the yellow ferric chloride solution with the Prussian blue produces the green shade. To avoid the formation of the green shade we tried the effect of acids other than hydrochloric acid. We obtained good results with sulfuric and nitric acids in different concentrations. Hence, these acids are recommended instead of hydrochloric acid.

¹ Greef, *Ber.*, 46, 2511 (1913).

Vorländer and Knight both filter off the iron hydroxides from the alkaline solution of sodium ferrocyanide and then acidify *before* adding the iron salt. This procedure may lead to a loss of hydrocyanic acid, since ferrocyanic acid oxidizes rapidly according to the following equation:

Influence of Ferric Iron on the Formation of Prussian Blue and on the Color of the Suspension.

It is to be noticed that Berl and Delpy, Lander and Walden, as well as Vorländer, used only ferrous sulfate for the formation of small quantities of Prussian blue. In the ordinary laboratory test for a cyanide, ferric chloride is also added, which changes the color to a greenish shade and makes accurate colorimetric determinations impossible. The addition of a ferric salt is not necessary, since enough of the ferrous salt is oxidized during the operation to furnish the ferric ions needed. According to our experience it is very important that there should not be a large excess of ferric salts present. Therefore, to prevent the oxidation of too much of the ferrous hydroxide to ferric, we remove most of the air from the solutions of the cyanide by means of a water vacuum pump.

In this connection we may quote Vorländer's statement.¹

"Die Meinung ist verbreitet, dass zum Zustandekommen des Berlinerblaus aus Ferrocyankalium die Gegenwart von Ferro- und Ferrisalz nützlich sei. Ich habe hierfür nicht das geringste Zeichen finden können."

Here one might obtain the misleading impression that Prussian blue is formed in the utter absence of a ferric salt. Vorländer probably means to say that the addition of ferric salt is unnecessary, as enough of the ferrous salt is oxidized by the action of atmospheric oxygen to furnish the ferric ions needed.

Influence of Heat on the Formation of Prussian Blue.

It is interesting to note that other workers apply heat in the test for a cyanide. Sometimes the alkaline mixture is heated, and sometimes heat is applied after adding the acid. Others recommend that the mixture be heated, both before and after the addition of acid. In testing by our method heat is not necessary if potassium fluoride is used. In using sodium chloride instead of potassium fluoride, or in the absence of these salts, gentle heat hastens the formation of Prussian blue.

Description of the Method.

As a result of our various experiments, we recommend the following procedure: Before concentrating the hydrocyanic acid solution, as in the case of a distillate, the portion to be tested should contain a slight excess of free sodium hydroxide. We used 0.02 to 0.1 g. This solution is then concentrated in a round bottom flask of 200 cc. capacity by using

¹*Ber.*, 46, 188 (1913).

a vacuum pump and condenser. The heat is supplied by immersing the flask in a water bath kept below 70° . To avoid any loss by spattering the flask is fitted to the condenser by means of an adapter such as is used in the Kjeldahl method for the determination of nitrogen. We concentrate until less than 1 cc. of liquid remains in the flask. Two-tenths to one-half cubic centimeter of 3% freshly prepared ferrous sulfate solution and about 0.05 g. of potassium fluoride are then added. The flask is exhausted at once by means of a water vacuum pump. The contents are mixed by rotating the flask. After 5 to 10 min. the flask is detached from the pump and the mixture acidified with 30% nitric acid. The blue color appears at once. Where only traces of hydrocyanic acid are present it is sometimes necessary to warm to about 50° in a water bath before the color appears. The suspension is then diluted to a volume that would give a color density convenient to compare with a suspension of Prussian blue made from a known weight of potassium cyanide. As a standard we used a suspension of Prussian blue made from 1 mg. of potassium cyanide. Such a suspension diluted to 25 cc. gave a color of convenient density. For comparison we used a Duboscq colorimeter.

If the cyanide solution to be tested was sufficiently concentrated so that further evaporation was unnecessary, the test could be made in a test tube. We kept the air out by means of a stopper and rotated the tube only enough to mix the reagents, allowing the mixture to stand 5 to 10 min. before acidifying. Much shaking must be avoided to prevent excessive oxidation of the ferrous hydroxide.

We ascertained the accuracy of our method by diluting 1 cc. of a standard solution of potassium cyanide to 25 cc. and evaporating under diminished pressure to 1 cc. When the residue was tested as described above we obtained the same quantity of Prussian blue as that formed by applying the test to 1 cc. of the undiluted standard solution.

The quantities of reagents mentioned are suitable for 1 to 2 mg. of potassium cyanide. If less than 1 mg. of potassium cyanide is present, the quantities of the reagents should be reduced accordingly. A large excess of reagents must be avoided in order to obtain the maximum density of color. When the analysis is carried out as described the maximum error should not exceed more than 1 part in 20. Thus in a plant giving 20 mg. of potassium cyanide per 100 g. of plant the results might vary by 0.001% if 100 g. of material are used for analysis.

Application as a Qualitative Test.

This method also proved to be a very delicate qualitative test for the presence of a cyanide. Owing to the possibility of obtaining a pure blue color we were able to detect with certainty 0.00002 g. of potassium cyanide, which represents less than 0.00001 g. of hydrocyanic acid.

Application to Microchemical Analysis.

The test for hydrocyanic acid was applied microchemically to sections of cherry bark and bitter almond with marked success. Sections or small parts of the material were treated with the reagents in a test tube according to our method.¹

Conclusions.

1. Dilute alkaline solutions of a cyanide can be concentrated under diminished pressure without appreciable loss of cyanide.
2. The maximum quantity of Prussian blue can be obtained from a cyanide only when the volume of the solution to be tested is sufficiently small, as has been indicated by Berl and Delpy and by Lander and Walden.
3. In the test for a cyanide it is better to acidify with nitric or sulfuric acid than with hydrochloric, since an excess of the latter tends to produce a green color.
4. Any considerable excess of ferric salts should be avoided in testing for a cyanide.
5. Application of heat is not necessary in testing for a cyanide by the method described.
6. The presence of certain salts, particularly potassium fluoride, in the liquid to be tested, has proved to be of great advantage.
7. The method furnishes a very delicate qualitative test for the presence of a cyanide.
8. The method is suitable for the estimation of very small quantities of a cyanide in distillates.
9. The test as described herein can be applied microchemically to sections of cyanogenetic plants.

A COMPARATIVE STUDY OF METHODS FOR THE QUANTITATIVE DETERMINATION OF SULFUR IN PEPTONE

BY HARRY W. REDFIELD AND CLARENCE HUCKLE.

Received January 18, 1915.

As a preliminary step to making quantitative determinations of the amount of sulfur in culture media, both before and after inoculation with sewage or water samples, and before and after incubation, a comparative study was made of those methods for the determination of sulfur in organic compounds which a search of the literature showed as having given the

¹ Further work is in progress on the application of this method to microchemical analysis.

best results in the hands of other investigators. Witte peptone was used as the sulfur-containing material and at least three determinations were made in each case, using two-gram portions of sample.

Methods for Total Sulfur.

The following methods for total sulfur were tried:

Liebig Method.¹—A slight modification of this method was also experimented with, using less heat and larger quantities of potassium nitrate in the fusions.

Osborne Method.²

A. O. A. C. Method.³

Liebig-Koch Method.⁴—After two trials of the method as described in the above reference, it was modified as follows:

The solution of the material, after the nitric acid treatment, was introduced into a nickel crucible containing eight grams of potassium hydroxide and about one-half gram of potassium nitrate and then evaporated over an alcohol lamp while a jet of air was allowed to impinge on the surface of the liquid. This resulted in a homogeneous mixture of the material under examination with the hydroxide and nitrate, thus precluding the tendency to burn which the peptone displayed in earlier determinations. Another device, trivial, but nevertheless worthy of note, was used in connection with the transference of the material, which had been treated with nitric acid, to the nickel crucible. A number of particles difficultly soluble in hot water clung tenaciously to the sides of the beaker. Obviously a rubber-tipped rod could not be used to loosen them because of the danger of minute particles of the rubber becoming detached which might contribute appreciable amounts of sulfur. Therefore, a small piece of filter paper on the end of a glass rod was employed for scrubbing. This effectively loosened all particles. The piece of filter paper with any adhering material was introduced into the nickel crucible and was, of course, destroyed during the alkali-nitrate fusion.

It was deemed advisable to ascertain whether any loss of sulfur in volatile form might take place during the treatment with nitric acid in the Liebig-Koch method.

For this purpose, a 250 cc. ether wash bottle was modified by fusing on a small separatory funnel. The lower end of the entry tube was drawn out and bent into a shepherd's crook. To the other tube, which emerged from the stopper of the wash bottle, was fused a piece of glass tubing which was bent so as to nearly reach to the bottom of a Fritz Friedrich's gas

¹ As described in "Organic Analysis," Sherman, 1912 edition, p. 298.

² THIS JOURNAL, 24, 142 (1902).

³ U. S. Dept. of Agr., Bur. Chem., Bull. 107, Revised, p. 23.

⁴ Chem. Zentr., 1886, p. 894.

wash bottle, the connection being made by means of a soft-rolled cork stopper. The glass tube which was fused into the stopper of the Fritz Friedrichs wash bottle was connected with a suction pump.

Two grams of peptone were placed in the ether wash bottle, which was mounted on a boiling water bath and connected to the Fritz Friedrichs wash bottle, into which 250 cc. of 12% potassium hydroxide had been introduced. Suction was applied and 20 cc. of nitric acid (sp. gr. 1.4) was introduced through the separatory funnel. The suction was so regulated that about two bubbles of air per second were drawn through the apparatus. Thus, any volatile compounds of sulfur which might be liberated during the process would be drawn into the potassium hydroxide solution and held there.

It required two weeks, running eight to ten hours a day, to completely distil all of the nitric acid from the ether wash bottle into the Fritz Friedrichs wash bottle.

The material in the ether wash bottle was then dissolved in hot water and transferred to a Jena glass beaker, acidified with hydrochloric acid, evaporated to dryness on a water bath, 20 cc. of distilled water added, again evaporated to dryness, heated for 4 hours in an air bath at 110° to dehydrate the silica, dissolved in water, 5 cc. of hydrochloric acid added, filtered, and the sulfur existing as sulfuric acid, precipitated and weighed as barium sulfate.

For comparison, the amount of sulfur existing as sulfuric acid after treatment of peptone with nitric acid in open beakers was determined.

For this purpose, 2 g. portions of peptone were placed in Jena glass beakers, 20 cc. of nitric acid (sp. gr. 1.4) were added to each, and digestion was carried on for two hours on a water bath; each solution was then evaporated to dryness, 20 cc. of distilled water added, again evaporated to dryness, heated for 4 hours in an air bath at 110°, dissolved in water, 5 cc. of hydrochloric acid added, filtered, and the sulfur existing as sulfuric acid precipitated and weighed as barium sulfate.

The close agreement between the results obtained in the closed system and in the open beakers, while not proving that there is no loss of volatile sulfur compounds, does prove that the length of time of the digestion with nitric acid above two hours has no effect, as the nitric acid was in contact with the peptone for two hours in the one case and for two weeks in the other.

To ascertain whether any loss had taken place during the nitric acid treatment in the closed system, the amount of sulfur in the solution contained in the Fritz Friedrichs wash bottle was determined.

For this purpose, the solution—which was calculated to contain 30 g. of potassium nitrate, resulting from the neutralization of the 18.3 g. of nitric acid distilled over from the ether wash bottle plus 14 g. of potassium hydroxide remaining from the 30 g. originally introduced in the form of 250 cc. of 12% potassium hydroxide, together with any potassium sulfide, potassium sulfite or potassium sulfate which might have been formed—was transferred to a large nickel crucible, evaporated to dryness and fused, in order that any sulfide or sulfite might be oxidized to sulfate. The fused mass was dissolved in water, an excess of hydrochloric acid added, evaporated to dryness, 20 cc. of distilled water added, again evaporated to dryness, heated for 4 hours in an air bath to 110° to dehydrate the silica, dissolved in water, 5 cc. of hydrochloric acid added, filtered, and precipitated with barium chloride in the usual manner.

The results showed that there was no formation of volatile sulfur compounds during the nitric acid digestion in the closed system; and since the results in the open beakers were in such close agreement with those obtained in the closed system in the matter of the percentage of sulfur revealed by nitric acid digestion, it is safe to assume that no loss of sulfur as volatile compounds occurs during nitric acid digestion in open beakers.

Petersen Method.¹

Perhydrol Method.—It was thought that very complete and rapid oxidation of the sulfur-containing organic compounds might be obtained by substituting perhydrol for the 3% hydrogen peroxide used in the Petersen method. Without giving the details of the methods employed, suffice it to say that—dissolving the peptone in water and then boiling with perhydrol—dissolving the peptone in alkaline solution and then boiling with perhydrol—digesting the peptone with nitric acid (sp. gr. 1.4) and then boiling with perhydrol, were all tried without success.²

Parr Calorimetric Method, employing for each charge a mixture of 1 g. of peptone, 15 g. of sodium peroxide and 1 g. of potassium chlorate.

Methods for Part of Sulfur Only.

Schultz Method, for loosely bound sulfur, described by Osborne.³

Nitric Acid-Potassium Chlorate Method.—The effect of a saturated solution of potassium chlorate in nitric acid was next tried upon peptone for the reason that it was believed that this reagent would give a measure of the *easily oxidized sulfur* present.

The method consisted in digesting 2 g. of peptone with 20 cc. of a saturated solution of potassium chlorate in nitric acid in a Jena glass beaker on a water bath for two hours, then evaporating to dryness, adding 5 cc. of hydrochloric acid and 20 cc. of water and evaporating to dryness, dehydrating, and determining the sulfur as barium sulfate.

Hydrochloric Acid-Potassium Chlorate Method.—Determinations were made using potassium chlorate and hydrochloric acid as the oxidizing agent.

Sulfur in Untreated Peptone.

The amount of sulfur precipitable as barium sulfate in a solution of peptone which had not been treated in any way was determined.

Results of Methods.

The average results for all of the foregoing methods appear in Table I.

¹ *Z. anal. Chem.*, 42, 406.

² This work was repeated by Miss M. I. Henkel several months later with the same results.

³ *THIS JOURNAL*, 24, 140 (1902).

Summary.

1. Of the methods tried, the Liebig-Koch method for total sulfur gave the highest and most consistent results.
2. During the preliminary treatment with nitric acid in the Liebig-Koch method no sulfur is lost in volatile form.
3. The length of time beyond two hours during which nitric acid is allowed to act has no influence in the Liebig-Koch method.
4. Of the methods for determining a part only of the sulfur, the Schultz method for loosely bound sulfur, and the digestion with nitric acid and potassium chlorate for easily oxidized sulfur gave the most consistent and most valuable results.

QUANTITATIVE DETERMINATIONS OF SULFUR IN THE CULTURE MEDIUM FOR THE DETECTION OF THE BACTERIA PRODUCING HYDROGEN SULFIDE.

BY HARRY W. REDFIELD AND CLARENCE HUCKLE.

Received January 18, 1915.

By the use of the methods which had been found to give the best results in the determination of sulfur in peptone, as presented in the preceding paper, a study was made of the total amount of sulfur broken down by the so-called putrefactive bacteria in an unadjusted culture medium, containing 3% of Witte peptone and 0.75% of potassium chloride after inoculation; of the forms of sulfur most readily used by them, and of the forms in which the sulfur existed after the action of the bacteria, whether as fixed sulfur, or as loosely bound sulfur, or as easily oxidized sulfur, or as a volatile sulfur compound such as hydrogen sulfide.

Sulfur in Insoluble Residue.—Determinations were first made of the total sulfur by the Liebig-Koch method in that part of the peptone which is agglomerated and which appears as an insoluble residue when peptone is boiled with water, in order to ascertain whether this material contained such a large amount of sulfur that its removal by filtration might have an effect upon hydrogen sulfide production.

It was found that so small an amount of sulfur would be removed in this way that peptone solutions may be filtered without detriment to the medium.

Peptone and Sulfur Used Up by Bacteria in Flasks of Different Size.—In order to ascertain the amount of peptone used up by the bacteria and also the amount of sulfur used in flasks of different size, when the simple peptone medium was inoculated with artificial sewage and incubated, 23 flasks of 100 cc. capacity were prepared by introducing into each, 10 cc. of 30% peptone solution and 5 cc. of 10% potassium chloride solution, after which the flasks were plugged, sterilized and capped and then 85 cc. of artificial sewage which had been strained through sterile cloth into a sterile beaker was added to each flask. Also one flask of 2000 cc. capacity was prepared by introducing into it 200 cc. of 30% peptone solution and 100 cc. of 10% potassium chloride solution after which it was plugged, sterilized and capped and 1700 cc. of the same strained artificial sewage added to it as was used in the 100 cc. flasks.

Two thousand cubic centimeters of a mixture of 30% peptone solution, 10% potassium chloride solution, and artificial sewage in the same proportions as was used in both the small and large flasks above mentioned, was prepared and sterilized to serve as a blank. The flasks containing the inoculated culture media were incubated for 48 hours at 38°.

Effect of Potassium Chloride and of Sewage on Sulfur Determinations.—The grams per 100 cc. of total solids, the grams per 100 cc. of total sulfur by the Liebig-Koch method and the grams per 100 cc. of easily oxidized sulfur by the potassium chlorate-nitric acid method, were immediately determined in the blank.

If the presence of potassium chloride and of artificial sewage has no influence on the sulfur determinations, then the grams of total sulfur per 100 cc. and of easily oxidized sulfur per 100 cc. divided by 3 and divided by 1.0110 (the specific gravity of a 3% peptone solution) and multiplied by 100, should be very close to 1.0061 and 0.5194, respectively, as found in the preceding paper.

Such computations actually give 0.9957 and 0.5176 and, therefore, it is proved that the Liebig-Koch method for total sulfur and the potassium chlorate-nitric acid method for easily oxidized sulfur are as accurate for the culture media employed as they are for peptone itself.

Sulfur in Cultures.—The cultures from 20 of the 100 cc. flasks were combined and filtered through a large webbed paper filter and the soluble material all washed through with distilled water; then a hole was punched in the bottom of the filter and the insoluble material was washed with distilled water into a tared beaker. The culture in the 2000 cc. flask was treated in like manner.

The soluble portions of the cultures were then evaporated to dryness to drive off all traces of volatile sulfur compounds, such as hydrogen sulfide; dissolved in hot water and made up to 500 cc., when total solids exclusive of potassium chloride, total sulfur and easily oxidized sulfur were determined in measured portions.

TABLE I.

The insoluble portions of the cultures were evaporated to dryness on the water bath and then dried in a vacuum desiccator over calcium chloride at 75° and weighed. As the amount of material was so small, no attempt was made to determine the easily oxidized sulfur, all of the material being used in each case for the determination of total sulfur. The results are given in Table I.

It should be noted that the ratio of total solids, exclusive of potassium chloride, to total sulfur, is very nearly the same in the soluble and insoluble portions of both cultures. Most of the insoluble material is probably peptone and, therefore, it is of no advantage to separate the soluble and insoluble parts of the cultures for analysis and consequently such a separation was not attempted in the subsequent work reported in this article.

Effect of Amount of Surface Exposed.—The fact that the total solids, exclusive of potassium chloride, total sulfur and easily oxidized sulfur were all markedly lower in the case of the cultures in the 100 cc. flask than in the case of the culture in the 2000 cc. flask demanded explanation. A possible reason was that in the case of 100 cc. flasks there was a greater amount of surface exposed to a greater amount of air and that, in consequence, the bacteria were more energetic and, therefore, decomposed a larger amount of peptone. This idea is at variance with the belief that the organisms producing hydrogen sulfide are anaerobes. In order to test out the validity of this explanation, two Fernbach culture flasks were prepared by introducing into each 500 cc. from a mixture of 400 cc. of 30% peptone solution, 200 cc. of 10% potassium chloride solution and 3400 cc. of strained artificial sewage; two flasks of 500 cc. capacity were prepared by introducing into each 500 cc. of the same mixture; ten flasks of 100 cc. capacity were prepared by introducing into each 100 cc. of the mixture, while the balance of the mixture was used as a blank.

The blank was immediately sterilized to await analysis, while the inoculated flasks of various size and shape were placed in the 38° incubator. Air was drawn through a wash bottle containing 5 : 1000 mercuric chloride solution to take out any hydrogen sulfide in the air, then through one of the Fernbach flasks. It finally passed through a Fritz Friedrichs wash bottle containing 2.5 g. of cadmium chloride in water solution, in order to catch and hold as cadmium sulfide all of the hydrogen sulfide which might be produced by the bacteria in the culture and swept over by the current of air. The speed of the air current was so regulated that one bubble per second passed through the wash bottles.

By means of a portable gas generator,¹ carbon dioxide gas under constant pressure was generated from calcium carbonate and hydrochloric acid and passed first through a wash bottle containing distilled water, then through the other Fernbach flask and finally through a Fritz Friedrichs

¹ A. W. Browne and M. J. Brown, *THIS JOURNAL*, 29, 859 (1907).

wash bottle containing 2.5 g. of cadmium chloride in water solution, to absorb any hydrogen sulfide, generated by the bacteria in the culture. The carbon dioxide generator was so regulated that one bubble of gas per second passed through the wash bottle.

The Fernbach flasks through which air and carbon dioxide, respectively, were being passed, and the other flasks through which no gas was being passed but which were being allowed to incubate in the usual manner, were all left in the 38° incubator for 48 hours. They were then sterilized by heat. Without filtering off the insoluble material, this having been proved to be unnecessary in the previous set of inoculations, the blank and the various cultures were analyzed for total solids, for total sulfur, for easily oxidized sulfur, for loosely bound sulfur by the Schultz method, and for sulfur as hydrogen sulfide.

For making these determinations, except that of sulfur as hydrogen sulfide, the blank and the various cultures were evaporated separately to small volumes, then each was made up to 250 cc. in a measuring flask and measured portions taken for analysis. For the determination of sulfur as hydrogen sulfide, the contents of the cadmium chloride wash bottles were acidified with strong hydrochloric acid, an excess of *N*/10 iodine added and the excess titrated with *N*/10 sodium thiosulfate. The results are given in Table II.

The amounts of total solids, exclusive of potassium chloride, remaining in the media after incubation proved that the bacterial action was most energetic in the Fernbach through which air was passed; next in the cultures having the greatest surface exposed, *i. e.*, in the 100 cc. flasks; next in the cultures in the 500 cc. flasks; and was least energetic in the Fernbach flask through which carbon dioxide was passed; while the amounts of total sulfur remaining, the difference between which and the total sulfur of the blank is a measure of the volatile sulfur compounds produced by the bacteria, proved that the production of volatile sulfur compounds by the bacteria decreased in the same order. Therefore, the orders for general bacterial activity and for hydrogen sulfide production were identical, and in the case of the flora with which this work was done, at least, the organisms producing hydrogen sulfide in largest amounts were aerobes and not anaerobes and for the maximum production of hydrogen sulfide, broad, low flasks giving the maximum surface of culture exposed to air should be used.

Determination of Hydrogen Sulfide.—The fact that the amounts of sulfur, as hydrogen sulfide, found by the method employed were far from being the differences between the total sulfur of the blank and the total sulfurs of the cultures in which sulfur as hydrogen sulfide was determined, demanded attention, as it indicated that the method which had been employed was faulty and that the cadmium chloride had failed to stop all of the hydrogen sulfide evolved. It was, therefore, decided to try an iodine solution instead of the cadmium chloride solution in the wash bottle.

For this purpose, air was drawn for 48 hours, first through a wash bottle containing lead acetate solution to remove any gaseous sulfur compounds, then through a Fernbach flask, containing 500 cc. of the culture medium, artificial sewage mixture

already described, in the 38° incubator, then through what had been calculated to be an excess of *N*/10 iodine solution in a Fritz Friedrichs wash bottle and finally through a *N*/10 sodium thiosulfate solution in a wash bottle.

During the period of incubation, the iodine solution was found to fade rapidly, indicating that larger amounts of hydrogen sulfide than had been expected were being produced, and consequently, small measured amounts of normal iodine solution were, from time to time, added to the iodine solution in the wash bottle. After 48 hours of incubation, the iodine solution and the sodium thiosulfate solution were mixed together, and the amount of iodine which had been used up, determined by titration.

It was found that an amount of iodine equivalent to the hydrogen sulfide which would be produced if nearly all of the sulfur of the medium were transformed to hydrogen sulfide, had been reduced. As determinations of total sulfur showed that only about 25% of the total sulfur had disappeared from the medium the results were evidently impossible. The explanation which is offered is that volatile, unsaturated organic compounds like

indol, $\text{C}_6\text{H}_7\text{N}$  and skatol, C_6H_7 ,

were liberated from the medium by the action of the bacteria and that these reduced the iodine solution.

The use of iodine solution having been proved to be of no value, it was decided to try solutions of cadmium chloride containing potassium chloride to prevent colloidal suspension of cadmium sulfide, of lead acetate containing potassium nitrate to prevent colloidal suspension of lead sulfide, of sodium peroxide and of potassium hydroxide, determining the total sulfur retained as sulfide by the Liebig-Koch method and not by liberating with hydrochloric acid and titrating with iodine and sodium thiosulfate solutions as had been done when cadmium chloride was before used.

The Fernbach flasks containing the usual mixture of culture medium and artificial sewage and the Fritz Friedrichs wash bottles containing the various solutions were connected in parallel to the same suction. The blank was immediately sterilized to await analysis and the Fernbachs were incubated at 38° for 72 hours (allowed to incubate 72 hours because the end of 48-hour period came on Sunday), air being sucked through the Fernbach flasks and their wash bottles at as uniform a rate as possible.

After 72 hours, each Fernbach was heated to boiling on a water bath for 30 minutes while air was sucked through it and its respective wash bottles. This was to drive out all hydrogen sulfide held in solution in the cultures. The solution from each Fernbach was then made up to 500 cc. (only a few cc. had been lost by evaporation in each case), and total solids, total sulfur and sulfur as nonvolatile sulfides determined in measured portions of these cultures and of the blank. The results are given in Table III.

The determination of sulfur as nonvolatile sulfides was accompanied by placing 300 cc. of each culture in a distilling flask and adding 25 cc. of concentrated hydrochloric acid. A Vigreux tube was attached and the solution was then distilled for 30 minutes under reduced pressure into sodium peroxide solution (5 : 60) contained in a wash bottle, the purpose being to decompose the sulfides and to distil the hydrogen sulfide formed into the sodium peroxide where it would be held as sodium sulfide, and possibly sulfate, in which form the sulfur was determined by the Liebig-Koch method.

The sum of the total sulfur remaining in the medium plus the sulfur found as hydrogen sulfide in the wash bottles proved to be 0.0294 g. per 100 cc. when cadmium chloride was used; 0.0245 when lead acetate was used; 0.0277 when sodium peroxide was used and 0.0302 when potassium hydroxide was used; in a number of determinations 0.0302 g. of total sulfur per 100 cc., on the basis of 3 g. of total solids exclusive of potassium chloride per 100 cc., had been found present in the blanks. The indications were, therefore, that potassium hydroxide stopped and held all of the volatile sulfur compounds evolved, while the other substances failed to do so, although cadmium chloride was almost as efficient.

Determinations of Hydrogen Sulfide with Shorter Incubation.—To eliminate the possibility of analytical errors having crept into this important determination, another exactly similar set of inoculations and sulfur determinations (with the exception that the cultures were incubated 48 hours instead of 72 hours) was made. The results are given in Table IV.

In this second set of determinations the results in all ways confirmed those of the previous work. The sum of the total sulfur remaining in the medium, plus the sulfur found as hydrogen sulfide in the wash bottles, proved to be 0.0304 g. per 100 cc. when cadmium chloride was used; 0.0243 when lead acetate was used; 0.0302 when sodium peroxide was used; and 0.0299 when potassium hydroxide was used: showing that cadmium chloride, sodium peroxide and potassium hydroxide were all efficient reagents to use, while lead acetate was not. In subsequent work, the three reagents named were all employed, although potassium hydroxide is preferable because the precipitate of cadmium sulfide tends to stick to the sides of the wash bottles, from which it must be dissolved by the potassium chlorate-nitric acid reagent with a possibility of sulfur being lost as hydrogen sulfide before it can be oxidized by the reagent, while there is a bad tendency toward spattering in the alkaline fusion when sodium peroxide is present, with possibility of loss. Neither of these difficulties is encountered when potassium hydroxide is used to catch and hold the volatile sulfur compounds.

It was very gratifying to have the sums of the volatile and nonvolatile sulfur compounds in the different cultures approximate so closely to the amount of total sulfur found in the blanks, as it showed that the analytical methods which had been adopted are capable of giving results which are surprisingly accurate when one considers the large number of operations, transferences and filtrations incident to the methods.

Mercaptans.—If mercaptans are formed by the action of the bacteria of sewage, they would pass over into the wash bottles, there to be held as metallic derivatives just as hydrogen sulfide would be held, and would be included under what has been designated sulfur as hydrogen sulfide. The amounts of mercaptans formed, if any, would undoubtedly be very

small and consequently no attempt was made to separate and determine them.

Sulfur in Alcohol Extract of Peptone and in Residue from Alcohol Extraction.—In order to ascertain whether the bacteria present in artificial sewage produce hydrogen sulfide more energetically or less energetically from those portions of peptone which are soluble in alcohol (containing lipid sulfur) and insoluble in alcohol (containing protein sulfur) than they do from peptone itself, culture media were made, in one of which the part of peptone insoluble in alcohol was substituted for peptone, and in the other of which the part of peptone soluble in alcohol was substituted for peptone. The portions of peptone soluble and insoluble in alcohol which were employed, were obtained in the course of the work described in the preceding article.

Hydrogen Sulfide Production from the Part of Peptone Insoluble in Alcohol.—Two Fernbach culture flasks were prepared by introducing into each 500 cc. from a mixture of 150 cc. of a 30% solution of the part of peptone insoluble in alcohol, 75 cc. of 10% potassium chloride solution and 1275 cc. of strained artificial sewage. The remaining 500 cc. were immediately sterilized and kept as a control to be analyzed. One of the Fernbachs was attached to a wash bottle containing sodium peroxide solution (15:225) and the other was attached to a wash bottle containing potassium hydroxide solution (20:225) arranged as previously described. One Fernbach flask to act as a check, was prepared by introducing into it 500 cc. from a mixture of 100 cc. of 30% peptone solution, 50 cc. of 10% potassium chloride solution and 850 cc. of strained artificial sewage. The remaining 500 cc. were immediately sterilized and kept as a blank to be analyzed. The Fernbach flask was attached to a wash bottle containing sodium peroxide solution (15:225).

The three Fernbachs were incubated for 48 hours at 38°, air in each case being sucked through a test tube containing the same solution as the respective wash bottle, then through the Fernbach flask, and finally through the wash bottle at as uniform a rate as possible. After 48 hours of incubation, each Fernbach was heated to boiling on a water bath for 30 minutes while air was sucked through it and its respective wash bottle. The solution from each Fernbach was then made up to 500 cc. (only 1 cc. to 2 cc. had been lost by evaporation in each case) and total solids, total sulfur, sulfur as nonvolatile sulfide and sulfur as hydrogen sulfide were determined in measured portions. In the determinations of sulfur as nonvolatile sulfide, the distillates were caught in 12% potassium hydroxide solution. The results of the analysis are given in Table V.

In both of the Fernbachs containing the medium made from the part of peptone insoluble in alcohol, much less hydrogen sulfide was produced than had been produced in media made from peptone itself. That this was not due to a less energetic bacterial flora in the artificial sewage than had been used in previous work, is proved by the fact that in the check Fernbach made up with the regular peptone medium and with the same sewage, the amounts of total solids exclusive of potassium chloride, total sulfur, sulfur as nonvolatile sulfide and sulfur as hydrogen sulfide, computed to the basis of 3 g. of total solids exclusive of potassium chloride per 100 cc. in the blank, were 2.7836, 0.0242, 0.0006 and 0.0059 g. per 100

cc., respectively, more than twice as much hydrogen sulfide having been produced as in either of the cultures containing the part of peptone insoluble in alcohol.

Hydrogen Sulfide Production from Part of Peptone Soluble in Alcohol.

—A set of inoculations was made using a culture medium made from the part of peptone soluble in alcohol.

Two Fernbach culture flasks were prepared by introducing into each 500 cc. from a mixture of 150 cc. of a 30% aqueous solution of the part of peptone soluble in alcohol, 75 cc. of 10% potassium chloride solution and 1275 cc. of strained artificial sewage. The remaining 500 cc. were immediately sterilized and kept as a control to be analyzed. One of the Fernbachs was attached to a wash bottle containing cadmium chloride solution (10:225) and the other was attached to a wash bottle containing potassium hydroxide solution (20:225) arranged as previously described. Two Fernbach culture flasks to act as checks were also prepared by introducing into each 500 cc. from a mixture of 150 cc. of 30% peptone solution, 75 cc. of 10% potassium chloride solution and 1275 cc. of strained artificial sewage. The remaining 500 cc. were immediately sterilized and kept as a blank to be analyzed. One of the check Fernbachs was attached to a wash bottle containing cadmium chloride solution (10:225) and the other was attached to a wash bottle containing potassium hydroxide solution (20:225) arranged as previously described. The four Fernbachs were then treated in the manner described on page 620. The results of analysis are given in Table VI.

In both of the Fernbachs containing the medium made from the part of peptone soluble in alcohol, much less sulfur-containing material was broken down and very much less hydrogen sulfide was produced than had been produced in media made from the part of peptone insoluble in alcohol, which in turn had given smaller amounts than had been found in media made from peptone itself. That this was not due to a less energetic bacterial flora in the artificial sewage than had been present in previous tests is proved by the fact that in the check Fernbach flasks made up with the regular peptone medium and with the same sewage, the amounts of total solids exclusive of potassium chloride, of total sulfur, of sulfur as nonvolatile sulfide and of sulfur as hydrogen sulfide, computed to the basis of 3 g. of total solids exclusive of potassium chloride per 100 cc. in the blank, were, in the cases where cadmium chloride and potassium hydroxide, respectively, had been used in the wash bottles, 2.8092, 0.0224, 0.0013, 0.0072 g. per 100 cc.; and 2.8430, 0.0242, 0.0006, 0.0064 g. per 100 cc.

Hence, it is evident that a medium made with peptone as the sulfur-containing material is a better one to use for the detection of the bacteria producing hydrogen sulfide than are media made with the part of peptone soluble in alcohol or with the part of peptone insoluble in alcohol.

Summary.

1. The percentage of sulfur present in the very small part of peptone which is insoluble in water is practically the same as in peptone itself. This explains why, in testing for bacteria which produce hydrogen sulfide, it makes no difference whether the medium is filtered or not.

2. The Liebig-Koch method for total sulfur and the potassium chlorate-nitric acid method for easily oxidized sulfur are as accurate for culture media made from peptone and potassium chloride as they are for peptone itself.

3. The ratio of total solids, exclusive of potassium chloride, to total sulfur is very nearly the same in the soluble and insoluble portions of cultures which have been inoculated with artificial sewage, containing bacteria which produce hydrogen sulfide, and incubated at 38° for 48 hours, and hence the indications are that the insoluble material is mostly peptone.

4. More material is broken down by the bacteria and more hydrogen sulfide is produced in flasks having much surface of the culture exposed to air than in flasks having comparatively little surface exposed.

5. It is noteworthy that, when sterile air was passed over the cultures, about 50% more total sulfur was converted into hydrogen sulfide than when they were exposed to quiescent air; and about 100% more than when sterile carbon dioxide was passed over them. Therefore, in the case of the flora which was used at least, the organisms were most active and produced the most hydrogen sulfide when supplied most freely with air. This fact would appear to be of great importance in connection with work directed toward the elimination of odors arising from septic tanks for sewage disposal.

6. From 25-30% of the total sulfur was converted into hydrogen sulfide when cultures were incubated 48 hours with sterile air passing over the culture, and from 50-60% when incubated 72 hours.

7. The volumetric iodine method for the determination of hydrogen sulfide is not available in the analysis of the gases given off by bacteria inoculated into the simple peptone medium, presumably because of the interference of volatile unsaturated organic compounds.

8. The use of potassium hydroxide is to be preferred for absorbing the hydrogen sulfide generated.

9. The sum of the sulfur remaining in the cultures after incubation plus the sulfur in gaseous form, which is practically all present as hydrogen sulfide, equals the total sulfur present in the cultures before incubation, when the determinations are made by the methods adopted in this investigation.

10. In media made from the part of peptone soluble in alcohol much less sulfur-containing material was broken down and very much less hydrogen sulfide was produced than was found in the media made from the part of peptone insoluble in alcohol, the ratios being about 3 : 5 and 1 : 6. In both of these media, very much less sulfur-containing material was broken down and very much less hydrogen sulfide was produced than in the simple peptone medium, the ratios being, respectively, about 1 : 2 and 1 : 20 in the soluble part of peptone, and 2 : 3 and 1 : 4 in the insoluble part of peptone.

11. As shown by the percentage of total solids exclusive of potassium chloride destroyed, and by the percentage of total sulfur converted into hydrogen sulfide, a larger percentage of sulfur-containing material than of total peptone was broken down, the ratio being about 3 : 1. The fact that the bodies of the bacteria were included in the total solids exclusive of potassium chloride, would not materially influence the ratio.

12. A larger percentage of easily oxidized sulfur than of total sulfur was converted into hydrogen sulfide by the bacteria, the ratio being about 4 : 3. It is evident that if a synthetic medium is to be prepared for the detection of the bacteria producing hydrogen sulfide, work upon which is herewith promised, that the sulfur should be introduced in an easily oxidized form.

13. A larger percentage of loosely bound sulfur than of total sulfur was converted into hydrogen sulfide by the bacteria, the ratio being about 3 : 2.

14. A very slightly greater percentage of loosely bound sulfur than of easily oxidized sulfur was converted into hydrogen sulfide by the bacteria, the ratio being about 10 : 9. There was about twice as much easily oxidized sulfur as there was loosely bound sulfur, both before and after the bacteria had acted upon the medium.

STUDIES ON AMYLASES. VIII. THE INFLUENCE OF CERTAIN ACIDS AND SALTS UPON THE ACTIVITY OF MALT AMYLASE.

By H. C. SHERMAN AND A. W. THOMAS.

Received January 2, 1915.

The reaction most favorable to the activity of malt amylase has been given as acid, neutral and alkaline, by different investigators, and there are also striking discrepancies in the statements regarding influence of salts. To some extent, though not entirely, the confusion has arisen through lack of (or failure to use) adequate or uniform criteria of neutrality.

Baswitz¹ observed that carbon dioxide increased the diastatic activity of malt extract. Later Mohr² confirmed the observation and found that very small amounts of lactic acid could also be used with beneficial effects.

Kjeldahl³ found that very small additions of sulfuric acid (making the reaction of the medium equivalent to 0.0005 N) increased the sacchar-

³ Dingler's *Polytech. Jour.*, 235, 379, 452 (1880).

ogenic¹ activity of malt extract, while slightly larger amounts were deleterious.

Detmers,² studying the amylolytic¹ action of malt extract, found slightly greater action on passing a current of carbon dioxide through the solution, or on adding small amounts of citric, phosphoric or hydrochloric acid.

Chittenden and Cummins,³ studying the action of malt extract upon a paste made from carefully washed potato starch, found the optimum activity in a neutral solution containing a small amount of peptone.

Duggan⁴ also reported neutrality as the optimum condition for the action of malt amylase, and in a second paper⁵ recommended the observation of optimum diastatic activity as a method of determining absolute neutrality—a suggestion which was later elaborated in the light of the ionization theory by Wood.⁶

Lintner⁷ likewise specified neutrality as the optimum reaction, while Reyckler⁸ recommended the addition of potassium acid phosphate and Effront⁹ reported activation of the enzyme by hydrochloric, hydrofluoric, sulfuric, and phosphoric acids as well as by acid phosphate. Effront further pointed out that the effect of adding free acid is largely dependent upon the purity of the starch and water employed. He was probably the first to realize the great importance of purity of materials in studying enzyme action. Petit¹⁰ also found slight acidity favorable and reported hydrochloric and lactic acids to show optimum activation at those concentrations which best favor the coagulation that occurs on heating a water solution of the enzyme.

Ford,¹¹ on the other hand, insists that malt amylase exerts its optimum activity in strictly neutral solution. He attributes the favorable effects, sometimes resulting from the addition of acids or acid salts, to neutralization of alkaline impurities in the starch or the malt extract used.

Schneidewind, Meyer and Münster¹² find acetic and citric acids favorable at a concentration of 0.001% but injurious at 0.01%. They also report

¹ These terms are used in preference to "saccharifying" and "liquefying" as explained in a previous paper.

favorable effects from very small additions of acid phosphate and of alum.

Maquenne and Roux¹ report that the maximum initial activity is obtained in solutions neutral to methyl orange, but that a solution alkaline to this indicator shows the optimum total digestion of starch into maltose and dextrin.

Fernbach and Wolff² find optimum amylolytic and saccharogenic activities in solutions neutral to methyl orange. Addition of secondary sodium phosphate to such solutions depressed the activity; primary sodium phosphate showed either no effect or a slight activation, the latter attributed by these authors to a failure to secure complete neutrality in the control solution.

Windisch and Derz³ found free sulfuric acid always harmful even in minute amounts, while primary potassium phosphate increased the activity of the amylase.

Heyl⁴ finds that primary potassium phosphate exerts both an activating and a conserving influence upon the enzyme, while neutral phosphate mixture depressed the activity of a freshly prepared malt extract, but increased that of an old extract. He concludes, however, that the activating effect of the phosphate is influenced by the proteins present in the malt extracts with which he worked.

Van Laer,⁵ working at 25°, found that acid phosphate and small additions of phosphoric, acetic, and tartaric acids increased the saccharogenic activity of malt extract without apparent effect upon the amylolytic action, while in parallel experiments with a commercial amylase preparation the addition of acid seemed always to retard the diastatic action, possibly due to a difference of reaction between the commercial preparation and the malt extract.

In view of the above discrepancies and the fact that experiments to test the influence of salts have usually been subject to uncertainty regarding the reaction of the medium, it seems unnecessary to review the earlier results obtained with salts at this time. Even the extended study by Hawkins⁶ which demonstrated an activation of amylolytic power by sodium and potassium chlorides is difficult to interpret in other respects because of the lack of neutrality in the digestion mixtures.

Experimental.

In view of the importance of an adequate knowledge of the influence of acids and salts on the activity of the enzyme and especially the definite determinations of the optimum hydrogen ion concentration, the following

series of experiments covering several acids and salts have been carried on in this laboratory during the past two years. The general plan has been to study one acid at a time, making a systematic series of quantitative determinations of diastatic power with increasing amounts of added acid until the optimum acidity is plainly exceeded and a distinct deleterious effect of the acid is observed, repeating the experiments in the region of the optimum with smaller increments of acid if necessary, in order to establish the optimum point with sufficient precision. The solution showing the optimum acidity was then exactly duplicated (except that no enzyme was added) and its hydrogen ion concentration determined by the electro-metric method.

Since previous workers have employed almost exclusively malt extracts which necessarily contained relatively large and variable amounts of salts and proteins, their results, even if concordant, would not have been conclusive. In the present experiments purified enzyme preparations were used which, while varying considerably in activity and in no case absolutely pure, were much purer and more active than any material available to previous investigators of the influence of acids and salts.

Materials.

Amylase.—The amylase preparations used were made in this laboratory by Miss M. D. Schlesinger as described elsewhere.¹ Before performing an experiment, an accurately weighed portion of the dry preparation would be dissolved in pure water and kept in an icebox at 7° to 8° until used.

Substrate.—The substrate used was soluble starch prepared from potato starch by the Lintner² method of treatment with dilute hydrochloric acid. Four samples of this starch were used, one as purchased and three after further purification. Their properties are as follows:

	Moisture. %.	Reduction. Mg. Cu_2O per 2 g. dry starch.	Acidity. Cc. of 0.01 <i>N</i> acid per 2 g. dry starch.
Starch 1.....	6.25	32.4	0.85
Starch 2 <i>a</i>	11.28	27.3	1.00
Starch 2 <i>b</i>	3.00	32.0	1.00
Starch 6.....	9.50	34.5	1.76

The "reduction" is the amount of cuprous oxide reduced by the starch when 100 cc. of a 2% solution are mixed with 50 cc. of Fehling solution and heated in a bath of boiling water for 15 min.

The acidity of the starch is determined by titration of a solution with 0.01 *N* sodium hydroxide, using rosolic acid as indicator.

Starch 1 was a commercial product. Starches 2*a* and 2*b* were prepared by repeatedly washing Starch 1 with distilled water. Starch 6 was also purified from a commercial preparation.

¹ THIS JOURNAL, 35, 1617-22 (1913).

² J. prakt. Chem., [2] 34, 378 (1886).

Water.—Ordinary distilled water was twice redistilled: first from alkaline permanganate solution into a reservoir whence it siphoned into a second flask from which it was distilled again. Phosphoric acid was added to this portion in order to hold any ammonia that might have come from the first distillation. Block tin condensers were used and the final distillate was caught in "Nonsol" bottles, contact with the air being avoided as far as possible.

Activating Agents.—These were carefully purified before trying their effect on the action of the amylase. The salts of the best obtainable grade were recrystallized three times, twice from distilled water and finally from triple-distilled water. The inorganic acids were of the purest "analyzed" reagent quality and were used directly as obtained from the manufacturers, it being deemed impracticable to purify them further. The organic acids were redistilled.

Apparatus.

Thermostat.—The digestions of starch by the amylase were carried out in a bath of ten gallons' capacity. The water in this thermostat was heated to, and kept at 40° by means of three 32 candle power carbon filament lamps, one of which burned continuously while the other two were in series with a relay and a large bulb of mercury containing a nickle contact wire in its narrow neck which served as the temperature control. This temperature regulator was very sensitive, keeping the bath within 0.02° above or below 40° . The water in the bath was stirred constantly and vigorously to ensure an even temperature throughout.

Glassware.—All glassware used to contain the starch solutions and digesting mixtures was kept filled with water when not in use, to avoid weathering and consequent introduction of alkali in the enzyme solutions, the danger of which has already been pointed out by Ford.¹ Before using the glassware each piece was carefully rinsed several times with tap water, then with distilled water and finally with triple-distilled water. The flasks or cylinders were then inverted to drain for a few minutes before using.

Hydrogen-ion Apparatus.—For the measurement of hydrogen ion the gas chain method was used in essentially the same manner as described by L. Michaelis.² A standardized Weston cell was used as the standard source of potential and a tenth normal calomel electrode was used in the hydrogen cell. A galvanometer was used instead of the electrometer described by Michaelis. For the hydrogen electrode, No. 14 gauge platinized platinum wire fused in glass tubing filled with a mercury connection was adjusted in the glass cell containing the solution, the hydrogen

¹ *J. Soc. Chem. Ind.*, **23**, 414 (1904).

² Abderhalden's *Handbuch der Biochemischen Arbeitsmethoden*, Vol. V, Part 1, pp

ion concentration of which was to be tested. This cell differed from Michaelis' in that a stream of hydrogen (washed by saturated mercuric chloride, strong potassium permanganate solution, strong alkaline pyrogallol, and passed through a tube of cotton to remove spray) was passed through it. Michaelis uses still hydrogen.

After finding the potential given by an unknown solution the hydrogen-ion concentration was found by referring to the chart plotted by S. P. L. Sørensen.¹ If this chart is not available the concentration can be calculated by means of the formula

$$\log H = -\frac{E - 0.3377}{0.0001983 T}$$

where H = concentration of hydrogen ion which we are seeking.

E = difference of potential in volts between the 0.1 N calomel electrode and the hydrogen electrode used.

T = absolute temperature.

The figure 0.3377 is the potential difference of the 0.1 N calomel electrode over the normal hydrogen electrode as determined by Sørensen at 18°.

Method of Determining Saccharogenic Power.

To determine the saccharogenic power an amount of soluble starch sufficient to make 600 cc. of 2% solution was weighed out and transferred to a beaker. Enough sodium hydroxide was added to neutralize the acidity of the starch and the mixture stirred to a paste with about 25 cc. of pure water. This paste was then poured into a 1 l. Erlenmeyer flask containing 300 cc. of boiling pure water, and the contents were boiled for two or three minutes to ensure complete solution of the starch. The flask was then partially cooled and the contents were adjusted to a volume of 420 cc. Seventy cc. were then poured into each of six 100 cc. graduated cylinders. The reagents whose effect on the saccharogenic power were to be determined were then added to the cylinders and the volume of solution in each cylinder was adjusted to the 100 cc. mark with pure water and the cylinders were then placed in the thermostat.

While the cylinders were resting in the water bath, the portions of enzyme solution were carefully measured into six 200 cc. Erlenmeyer flasks by means of a 1 cc. pipet which is accurately standardized and graduated to 0.01 cc. These small Erlenmeyer flasks were then placed in a brass rack and the contents of the cylinders were poured into their respective flasks at intervals of 10 sec. and the rack of flasks with their digestion mixtures placed at once in the water bath. At the expiration of 30 min., 50 cc. portions of mixed Fehling solution were poured quickly into each flask at 10 sec. intervals, corresponding with the addition of

¹ *Comptes-Rendus des Travaux du Laboratoire de Carlsberg*, Vol. 8, 1re Livraison, 1909; also *Biochem. Z.*, 21, 131; 22, 352 (1909).

the starch solution to each flask, so that each mixture had digested for exactly 30 min.

The rack was then placed in boiling water for 15 min., after which the contents of the flasks were filtered through Gooch crucibles with suction. The precipitated cuprous oxide was carefully washed with hot water, followed by alcohol and finally ether. The crucibles were dried in an oven and weighed. After the weight of cuprous oxide, due to the reducing power of starch, is deducted from the total, the saccharogenic power is calculated from the scale of Sherman, Kendall and Clark.¹ Blank experiments showed that the acids and salts studied were all without effect upon Fehling solution.

Data of Typical Experiments.

In order to present the results of the experiments as concisely and clearly as possible, no attempt will be made to record every quantitative

determination, nor to give the data in the order in which they were determined. The object is rather to give the data of the principal experiments in sufficient detail to show the nature of the evidence and in such order as to simplify the discussion.

The data showing influence of acids upon saccharogenic activity are tabulated first.

The optimum solution in the case of acetic, is that one containing 3.0 cc. of 0.02 *N* acetic acid per 100 cc. of 2% starch solution, which in terms of total concentration of acetic acid is 0.0006 *N*. Measurement of hydrogen ion concentration in such a solution of acetic acid and soluble starch gave the Sørensen exponent $p_H^+ = 4.2$.

The optimum concentration of propionic acid is 0.001 *N*. The determination of hydrogen ion in a propionic acid starch solution of this concentration showed $p_H^+ = 4.4$.

¹ As explained above, under "Method of Determining Saccharogenic Power," the added acid is contained within the final volume of 100 cc., the volume and the concentration of starch of the completed digestion mixture being the same in all cases.

In the experiments with acetic and propionic acids recorded in 1 and 2 of Table I the enzyme 46B and the Starch 2a were used throughout. Of the experiments with phosphoric acid which follow, the first series (3) was made with the same enzyme and starch while in the second series (4) both the enzyme and the starch were different, and in the third series (5) still a different enzyme preparation was used, but the starch was the same as in the second series. The purer enzyme preparation gave a lower initial and a higher optimum power but the optimum concentration of acid was the same in the three cases.

In the case of phosphoric acid it will be noted that the optimum activity is found in a solution containing this acid in the concentration of 0.0005 *N*. Measurement of hydrogen ion in this solution showed $p_H^+ = 4.6$.

Inasmuch as the activity was hardly appreciably diminished at a phosphoric acid concentration of 0.00054 *N*, the hydrogen-ion concentration was also measured at that point and found to be $p_H^+ = 4.5$.

Passing now to the experiments with strong acids, it will be seen from the table that hydrochloric acid was tested with the same starch as was used with acetic, propionic and the first series with phosphoric and with a very similar enzyme preparation. The first series with nitric employs the same enzyme and starch as the acetic, propionic and (first) phosphoric; the second series with nitric corresponds exactly in starch and enzyme used, with the second series of experiments on phosphoric. The first series with sulfuric corresponds to the experiments with hydrochloric and the second series with sulfuric to the first with nitric. It is therefore believed that the results obtained with the six different acids are fairly comparable with each other and at the same time adequately safe-guarded against any constant error such as might have been possible had all work been done with one sample of enzyme or of starch.

In Series 6, Table I, the optimum concentration of hydrochloric acid was 0.0002 *N*. The soluble starch solution to which hydrochloric acid had been added to this concentration showed $p_H^+ = 4.2$.

With amounts of acid above the optimum the depression of the power is naturally much greater than for corresponding excesses of the weaker acids.

For nitric acid the optimum point is again found in the 0.0002 *N* concentration of acid, and the activity rapidly falls off in the solutions having a greater concentration of acid. Measurement of hydrogen ion in the optimum solution showed $p_H^+ = 4.4$.

As in the case of hydrochloric acid, the optimum activity with sulfuric acid is obtained in solution having a concentration equal to 0.0002 *N*. Measurement of hydrogen ion in this optimum solution showed $p_H^+ = 4.3$ to 4.4.

Closely connected with the problem of the influence of the acids is that of their neutral salts. Sodium and potassium chlorides, nitrates, and

sulfates have therefore been studied, as well as the primary phosphates which, being both salts and acids, will be considered later. In addition to what has been said above regarding the findings of earlier workers it should be stated that Osborne, in 1895, pointed out¹ that the addition of a small amount of sodium chloride assisted his purified malt amylase preparation to exert its true diastatic power.

In our experiments it has been observed that so long as commercial soluble starch, even of high grade (Starch 1) was used as substrate, the small additions of the salts above mentioned have very little effect, but when the more highly purified soluble starch was used the effect was considerable as will be seen from the tables which follow.

Limitations of solubility and a tendency to salting out of the starch when treated with the Fehling solution precluded experiments at higher concentrations than are shown in the tables.

In the case of the primary sodium phosphate it will be seen that the optimum activities observed were at 0.06 *M*.

Since, as already explained, the experimental method did not permit of carrying the comparison to concentrations higher than 0.06 *M*, the possibility of activation still higher than shown at that point is not excluded, but the form of curve obtained on plotting the results makes it probable that approximately the optimum activation is reached at 0.06 *M*.

Measurements of hydrogen-ion concentration in 0.06 *M* sodium and potassium acid phosphates gave Sørensen exponents of 4.6 and 4.2, respectively.

¹ The indicated amounts of reagent solutions are included within the final volume of 100 cc. which, as explained above, was the same in every case.

The Influence of Acids and Salts upon the Amyloclastic Action.

Determination of Amyloclastic Power.—For determination of amyloclastic power of the amylase a procedure based upon the method of Wohlgemuth¹ was used. This procedure is as follows: Forty-two test tubes very carefully cleaned and dried are placed in a special wire frame or basket and the whole set in a bath of ice water. Then 2.5 cc. of 2% starch solution are carefully measured into each of the tubes by means of a buret which has a very long delivery tip reaching to the bottom of the test tube, thus avoiding the lodging of any of the solution on the sides of the tube.

To the starch solution in the tubes the solution of activating agent is added in the same manner, then enough pure water is added to each tube to make the final volume exactly 5 cc. and the concentration of starch 1%. After each addition of activating agent and water the tube is shaken to mix thoroughly. Very carefully measured portions of enzyme solution are now introduced into each tube and the tube agitated to ensure a perfect mixture. No reaction takes place because the solutions are kept cold by the ice water in which the basket of tubes rests.

The basket of tubes is transferred from the ice water to the constant temperature 40° bath and at the expiration of 30 min. is taken out and placed in the ice water to stop the action. Thus the tubes are subjected to an average temperature of 40° for 30 min. After a few minutes 0.1 cc. of 0.1 *N* iodine in potassium iodide solution is added to each tube. It is extremely important that the same amount of iodine solution be added

to each tube since variation in the iodine concentration will give serious differences in color value. In this laboratory a dropping bottle is used that delivers drops of 0.1 cc. volume. About 20 cc. of distilled water are then poured into each tube, filling it within about 2 cm. of the top, and the contents thoroughly mixed. Each given set of tubes (containing the same amount of added reagent) is then observed for the end point, *i. e.*, the tube of lowest enzyme concentration which shows none of the familiar blue or violet color due to starch, and the weight of 1% starch solution, 5000 mg., is divided by the weight in milligrams of enzyme present to give the numerical value of the amylolytic power of the enzyme.

125,000						

* The asterisk designates the end point tube.

For example, six portions of enzyme solution containing 0.2 mg. per cc. were measured into six tubes as follows: 0.3 cc., 0.4 cc., 0.5 cc., 0.6 cc., 0.7 cc., and 0.8 cc. After carrying out the procedure just described the following colors were obtained: 1, Blue; 2, Blue; 3, Red-Violet; 4, Violet-Red; 5, Red; 6, Orange-Red. The Wohlgemuth end point was reached in tube No. 5. This tube contained 0.7 cc. or 0.14 mg. of enzyme, therefore the power for 30 min. digestion at 40° (D_{30}^{40}) is equal to $5000/0.14 = 35,714$ or in round numbers 35,700.

* The asterisk designates the end point tube.

† In these cases the quality of colors was such that the end point was judged to be half-way between the two tubes.

In testing the effect of any reagent to be examined, six or seven tubes are ordinarily tested with the same amount of reagent but with varying amounts of enzyme solution. Seven or six such sets of tests, each set containing a different amount of reagent, are made for every reagent to be examined. Hence each set of tubes contains the same concentration of reagent whose effect is to be determined, but differing concentrations of enzyme while the several sets of tubes differ from each other in that they contain varying concentrations of activating agent.

† In these cases the quality of colors was such that the end point was judged to be half-way between the two tubes.

¹ The terminology used in describing the colors is that of the Milton Bradley Standard Color Chart as given by Mullikin in his "Identification of Pure Organic Compounds."

² End point was found with 1.5 mg. enzyme.

studies of other amylases in which the results are similarly expressed, such as those of Long and Johnson.¹

Another reason is that to judge of the amylolytic activity of a purified preparation of malt amylase on the basis of the Wohlgemuth end point exclusively is likely to be misleading because of the relative persistence of material giving a slight blue or violet iodine reaction when starch is digested by preparations of this character. Thus in the case of the example given above, while the Wohlgemuth end point was found in tube 5 containing 0.7 cc. of enzyme solution or 0.14 mg. of the enzyme preparation, yet in tube 3 having 0.5 cc. or 0.10 mg. there was no

¹ THIS JOURNAL, 35, 895 (1913).

typical starch-iodine blue. If this were taken as the end point the power of the enzyme would be 50,000 or about 40% higher. Examination of the color readings in Tables XVI will show that in many, if not in most, cases the amount of enzyme required to carry the digestion to the "red" end point is one-third to one-half greater than that which carries it to the disappearance of the typical "blue." In view of the fact that this point has been dealt with in a recent paper from this laboratory,¹ it need not be further discussed here, nor in connection with the tables which are given:

There is no apparent activation of the amylolytic action by the addition of acetic acid, but beyond the concentration at which the optimum saccharogenic action was obtained there is depression of the amylolytic as of the saccharogenic power.

The results in Table IV are closely analogous to those just noted in the case of acetic acid.

with phosphoric acid there is a distinct activation. It will be noted that the optimum concentration of phosphoric acid for amylolytic action as judged by the Wohlgemuth end point is much lower than the optimum for saccharogenic activity. Attention may also be called to the persistence of colors intermediate between blue and red which has already been referred to at the top of the page.

For HCl, as in the case of phosphoric acid, the optimum is much lower than for saccharogenic action and the concentration which gives optimum saccharogenic action has a distinct inhibitory influence upon the amylolytic action as measured by this method. The unsatisfactory nature of the end point is again apparent.

What has been said of the influence of hydrochloric acid upon amylolytic action will be seen to apply also to nitric and sulfuric acids.

In the case of the acid phosphates, as of the free acids and the neutral salts, optimum amylolytic activities, as measured by the Wohlgemuth

method, are reached at concentrations much lower than those which give optimum saccharogenic action, and the latter concentrations distinctly depress the amylolytic action.

Summary.

The effects of acetic, propionic, phosphoric, hydrochloric, nitric and sulfuric acids, and the chlorides, nitrates, sulfates and primary phosphates of sodium and potassium have been determined. Special reference to the determination of concentrations favoring optimum activity of malt amylase.

Previous studies made in this laboratory, showing that the measurement of amylolytic action by determining the conditions under which the starch-iodine end point occurs, gives with purified malt amylase results which are of little value compared with those obtained by the measurement of the saccharogenic action, have been confirmed. Full data of the amylolytic action have been given in the foregoing text. The conclusions which follow refer, except as otherwise explained, to the saccharogenic action.

Special attention has been given to the purification of the amylase preparations, the starch, the activating agents, and the water used. While we have not, as in the case of pancreatic amylase, observed any case of complete inactivation of the enzyme through deficiency of electrolyte alone, it is plain that the activities shown by purified materials in the absence of added electrolytes are to be regarded as abnormally low.

All of the electrolytes above mentioned increased the activity of malt amylase. The activities observed at the optimum concentrations of these different activating electrolytes varied from less than double to more than thirty-fold the corresponding activities in the absence of the electrolyte; depending chiefly upon the purity of the enzyme preparation and the starch employed. In comparing the activating influence of different electrolytes more weight should be attached to the maximum saccharogenic power demonstrated in the case of each electrolyte by the same enzyme preparation than to the increase of power above that shown when no electrolyte was added.

In those cases in which the use of the same enzyme permits comparison of results obtained in different series of experiments, it appears that the acids had a greater activating influence than the neutral salts, while the acid phosphates of sodium and potassium gave as high an activation as did any of the free acids. The main object held in view in the arrangement of the experiments was, however, not to compare the acids and salts with each other but to establish the optimum concentration of each of the activating agents considered separately, and particularly the optimum of each acid in terms of hydrogen-ion concentration.

The weak acids (acetic, propionic, phosphoric), the strong acids (hydro-

chloric, nitric, sulfuric), and the acid phosphates of sodium and potassium, all showed optimum activation in those concentrations which have essentially the same actual acidity. This optimum hydrogen-ion concentration, as determined by the electrometric method and expressed by Sørensen's exponent, was found in each case between the limits p_H^+ 4.2 to 4.6.

Additions of free acid in concentrations greater than the optimum have a marked depressing influence upon the activity of the enzyme which is naturally more striking in the case of the stronger acids. Acetic and propionic acids in quantities ten times the optimum decrease the activity about one-half; hydrochloric, nitric and sulfuric acids reduce the activity more than one-half when present in concentrations two and one-half times the optimum, while in presence of five to eight times the optimum of these strong acids the enzyme action was almost entirely destroyed. In determining the diastatic power of malt preparations, acid phosphate may conveniently be used to ensure activation with little danger of excessive acidity.

Whether the activating agent be an acid or a salt, the amyloclastic action, as measured by the Wohlgemuth method, reaches an optimum at a concentration of the activating agent much below that which gives optimum saccharogenic action. Those concentrations which give the optimum saccharogenic activity are so far above the optimum for amyloclastic action (Wohlgemuth method) as to show a distinct inhibitory influence.

We desire to express our indebtedness to the Carnegie Institution of Washington for use of malt amylase preparations which had been purified in connection with investigations conducted by aid of its grants and described in other papers from this laboratory.

For the data given in Tables X and XVI we are indebted to our former associate, Dr. C. F. Hinck.

STUDIES ON AMYLASES. IX. FURTHER EXPERIMENTS UPON THE PURIFICATION OF MALT AMYLASE.

By H. C. SHERMAN AND M. D. SCHLESINGER.

Received January 25, 1915.

In continuing our experiments upon the purification of malt amylase¹ the operations of precipitation, solution, and dialysis which are involved in the purification process have been studied in some detail, with a view to determining quantitatively the loss of diastatic power at each step and,

¹ THIS JOURNAL, 35, 1617-23 (1913).

if possible, finding means to control these losses so as to secure a definite product of maximum activity.

In fractional precipitation with alcohol the greatest destruction of enzyme usually occurs in the first precipitation. Losses in the final precipitation with alcohol and subsequent drying in partial vacuum were found to be less serious than might be expected from the statements of some previous writers. In general, the largest losses of diastatic power occurred during dialysis, but since dialysis is the best available means of separating certain impurities from the enzyme it has not been found practicable to eliminate this step from our purification process. That the loss of activity which occurs during dialysis is not due in any large measure to the passage of the enzyme as such through the dialyzing membrane is shown by examination of the dialysate for diastatic power.¹

Osborne's theory of the chemical nature of the enzyme² affords a possible explanation. If, as Osborne suggested and as our experiments also indicate, the enzyme is a compound of an albumin with a proteose or peptone, which compound is hydrolyzed on heating in water, it would seem probable that a fraction of the enzyme would be hydrolyzed in water solution even at low temperatures. The removal, then, of one of the products of hydrolysis (*i. e.*, the proteose or peptone) by dialysis would result in a further hydrolysis of the enzyme and loss of diastatic power in the solution undergoing dialysis without any accumulation of enzyme in the dialysate. Quantitative experiments upon the loss of activity in dialyzed solutions of the purified enzyme, as contrasted with duplicate solutions kept at the same temperature but not submitted to dialysis, will be described in our next paper.

From the temperature coefficient of such hydrolytic reactions and the decreasing ionization of water on cooling, the hypothesis that the loss of activity during dialysis is chiefly due to hydrolytic destruction of the enzyme leads one to expect, what has now been fully established in our experience, that when the dialysis is conducted at ice-box temperature the loss of diastatic power is much diminished while the removal of impurities through the membrane is but little retarded.

Thus, notwithstanding the relative stability of malt amylase solutions in ordinary conditions at room temperature, it is important that the dialysis of such solutions for the removal of impurities be conducted at lower temperature.

As starting material in many of our recent purification experiments we

¹ In a considerable proportion of the cases tested, the dialysate shows some diastatic activity. As this is not only small in comparison with the total loss during dialysis but also very irregular, it is uncertain whether it should be attributed to anything more than imperceptible defects in the membrane.

² THIS JOURNAL, 17, 587-603 (1895); 18, 536-542 (1896).

have used a concentrated malt extract made¹ by evaporating an infusion of pale malt *in vacuo* on a commercial scale, with stirring to prevent the solution from being heated above 40° in contact with the warming surface. Two such products were used.

Extract No. 1 had a specific gravity of 1.27 and contained 7% of alcohol as a preservative. This concentrated extract had been found capable of forming 17.6 times its weight of maltose from a surplus of 3% arrowroot starch paste in 30 minutes at 37.5°.

Extract No. 2 was from the same malt infusion as the above but was still further concentrated *in vacuo* to a specific gravity of 1.39. It contained only 4% of alcohol as preservative and had been found able to produce 23 times its weight of maltose in 30 minutes under the conditions just given in describing Extract No. 1.

The following illustrates the purification method which we have usually employed when starting with such extracts: One liter of the concentrated malt extract is divided into twenty equal portions, each of which is placed in a collodion sac of 500 cc. capacity. The twenty sacs are suspended in 30 liters of water in an ice-jacketed metal tank, the dialysate being maintained at a temperature of 5-10° and allowed to dialyze for 24 hours. In sufficiently cool weather the dialysate is slowly but constantly renewed by means of a current of tapwater running at the rate of 800 cc. per minute; when the tapwater is too warm to permit the use of a constant stream, the dialysate is changed two or three times during the twenty-four hours. At the end of this dialysis the sacs always contain a deposit of material which has precipitated with the removal of dialyzable substances from the solution. This insoluble material, which is without diastatic power, is separated by decantation (with the aid of the centrifuge if necessary) and rejected. To the clear solution from the sacs (which in this case had increased to about three times its original volume) crystallized ammonium sulfate is added in the proportion of 45 g. to 100 cc., the solution being kept in an ice-bath and stirred almost continuously until the crystals have dissolved (usually about 15 minutes); the precipitate produced by ammonium sulfate is then settled by means of the centrifuge, the liquid decanted and rejected, and the precipitate dissolved in 500 to 600 cc. cold water. This solution is divided between four 500 cc. collodion sacs and dialyzed as before for about twenty hours, again decanted from sediment, and then treated with an equal volume of (cold) pure alcohol (99.8%) keeping the temperature below 15°. The material precipitated by this amount of alcohol is separated by means of the centrifuge and rejected.² To the liquid enough more cold alcohol is added to make the alcohol

¹ This extract was kindly prepared for us by Dr. C. Von Egloffstein of the American Diamalt Company to whom, as also to Mr. Kaltenbach and Dr. Schulhof of the same company, we desire to express cordial thanks for courtesies and coöperation.

² This is the material which we have sometimes referred to as "50% precipitate."

content 65% (by volume). The precipitate thus obtained is separated by means of the centrifuge, and dried on a watch-glass in partial vacuum over sulfuric acid in the dark, at a temperature not exceeding 15°.

As will be seen from the abstract of experimental data below, this method of preparation has in several cases been changed for experimental purposes but without resulting in a better product.

The twenty-two preparations made essentially as above described showed diastatic powers ranging from 760 to 1570 (new scale) equivalent to about 1200 to 2350 on Lintner's scale. Thus both the minimum and the average powers are much higher than in the previous year's work; the maximum powers found during the past year are essentially the same as those recorded a year ago.

That a marked advance in the average result did not lead to any increase in the maximum previously observed suggests that the six most active preparations, having powers of 1430 to 1570 (new scale) equivalent to 2150 to 2350 on Lintner's scale, may approximate the maximum activity obtainable by this method of purification. It may also be noted that these products were obtained not only at intervals of several months but also from different materials; 3 of the preparations from kiln-dried pale malt, 1 from green malt, and 2 from the malt extracts described above. Nevertheless it appears probable, for reasons given in this and the following paper, that all the preparations contain inactive albumin in addition to the enzyme itself.

Brief descriptions of the various preparations made during the past year will be given at the end of the paper. *

Our most active preparations, made as above described, contain 15.1–15.3% of nitrogen in the dry ash-free substance. Osborne's most active preparation, showing diastatic power of 600 Lintner, contained 16.1% nitrogen. His other preparations varied considerably both in power and in nitrogen content.¹ On account of the fact that our determinations of nitrogen were necessarily made upon very small amounts of material, and in view of the differences in nitrogen content among the various preparations described by Osborne, we do not attach any exact quantitative significance to the difference in the apparent percentages of nitrogen, but conclude simply that our preparations have a slightly lower nitrogen content than Osborne's. The principal difference in the methods by which Osborne's product and our own were obtained is that Osborne dialyzed for several days, apparently at the temperature of the room or of tap-water, while we dialyzed for not over forty-four hours in all and at a temperature below 10°. On following Osborne's general method, we obtained a preparation having practically the same nitrogen content and diastatic power as Osborne's most active product. (Our preparation

¹ THIS JOURNAL, 17, 591–99 (1895).

124B with 16.0% of nitrogen and a diastatic power of 660 Lintner.) We attribute this increase of nitrogen content and decrease of power to the prolonged dialysis. In accordance with the theory of the constitution of the enzyme and its hydrolysis in solution outlined above, the higher nitrogen and lower power of the products obtained when dialysis is prolonged are explainable as due to the hydrolysis of the enzyme and the removal of the dialyzable constituent. This dialyzable constituent (proteose or peptone) being a hydrolytic product may be expected to contain a lower percentage of nitrogen than the enzyme as a whole. The corresponding albumin-fraction would thus contain more nitrogen than the enzyme as a whole.

In the case of our preparation IIIB the coagulum contained 16.1% nitrogen and the uncoagulable matter 13.7% nitrogen. While Osborne did not analyze the coagulated albumin obtained on boiling the solution of his enzyme, he has elsewhere¹ given an analysis of malt albumin which shows 16.71% of nitrogen.

It therefore seems probable that the lower nitrogen content and higher diastatic power of our best preparations are both due to the fact that the loss of the peptone or proteose fraction of the enzyme has been minimized by restricting the time and lowering the temperature of the dialysis.

It should be stated, however, that on examining one of our most active preparations (IIIB) we found it to contain slightly more coagulable albumin than did Osborne's most active preparation. It is possible that our methods of purification, while minimizing deterioration and yielding a more active product, may be less efficient than Osborne's in freeing the enzyme from some albumin which accompanies it in the malt. The problem of the chemical nature of the enzyme is discussed further in our next paper.

Abstract of Experimental Data.

Numbers 74²-76 were preliminary experiments upon a sample of concentrated extract.

Numbers 77-95 were experiments devoted to the study of losses of diastatic power at different steps in purification.

Preparation 96: Malt was extracted with 2½ times its weight of cold water for one-half hour, the extract pressed out and filtered, then precipitated with ammonium sulfate and centrifuged, the precipitate dissolved in cold water and dialyzed in collodion sacs against cold distilled water, the solution then filtered and precipitated with alcohol as described above. Power 1170 (new scale).

Preparations 97, 98, 99³ and 101 made in practically the same manner as the preceding, showed powers of 830, 762, 1140, 780, respectively (new scale).

Preparation 102: Malt was extracted with 2½ parts of 10% ammonium sulfate for 1 to 2 hours, pressed and filtered, dialyzed for 23 hours against 10 volumes of cold distilled water with one change of dialysate; freed from sediment by means of the centri-

¹ THIS JOURNAL, 18, 556 (1896).

² Numbers 1-73 are outlined in THIS JOURNAL, 35, 1620-22 (1913).

³ Preparation 100 was lost in drying.

fuge, then precipitated with ammonium sulfate and the preparation completed as described in the early part of this paper. Power 1572 (new scale).

Preparations 103 and 106 made in the same manner as preparation 102 showed powers 1340 and 1110, respectively (new scale).

In Experiments 104, 105, 107, 109 variations of method were tried without satisfactory result.

Preparation 108: Like 102 except that the original extraction was with 2% neutral lead acetate. Power 790.

Preparation 110: Like 102. Power 1010.

Preparation 111A was made from concentrated malt extract No. 1 as already described in the text. Power 1100; nitrogen in dry, ash-free substance, 15.2%. As the volume of solution became during dialysis too large to be handled as one preparation, a portion was set aside in the ice-box for several hours and then completed in the same way. This product, called **111B**, had a power of 1470¹ and a nitrogen content (in dry, ash-free substance) of 15.2%. The yield of preparation 111 (**A** and **B**) was 2.23 g., obtained from 2 liters of the concentrated malt extract.

Preparation 112: 350 cc. of the same concentrated extract (No. 1) treated as in Preparation 111A yielded 0.8 g. with power of 900.

Preparations 113 and 114 were made from extract No. 2; otherwise practically duplicates of 111A; yields 0.22 and 0.23 g. per 100 cc. of original concentrated extract; powers 1020 and 1030, respectively.

Preparations 115 and 116 were made side by side from concentrated extracts Nos. 1 and 2, respectively. The first yielded 0.16 g. per 100 cc. with power of 800; the second, 0.24 g. per 100 cc. with power of 1050.

Preparations 117 and 118 were made from extract No. 2, duplicating the conditions which obtained in the case of preparations 111A and 111B, respectively. Yields per 100 cc., 0.14 and 0.24; powers 1455 and 1340, respectively.

Preparation 119: Like 117; yield 0.27 per 100 cc.; power 1185.

Preparations 120-122: Unsuccessful attempts at further purification by reprecipitation and repeated dialysis. Not only was most of the diastatic power destroyed but the material underwent changes which diminished its solubility both in water and in 50% alcohol. Preparation 122, which had been twice precipitated by ammonium sulfate as an additional precaution against retention of carbohydrate, contained 15.2% nitrogen in the dry, ash-free substance and showed a power of 470.

Preparation 123 was made from extract No. 2 in the same manner as Osborne's Precipitate XIII (*THIS JOURNAL*, 18, 539-40 (1896)), except that in dialyzing the temperature was kept below 15° and collodion sacs were used instead of parchment. Yield, 0.13 g. per 100 cc.; power, 105; nitrogen in dry ash-free substance, 15.1%.

Preparations 124A and 124B, made from extract No. 1, were obtained in essentially the same manner in which Osborne obtained his Precipitates III and IV (*THIS JOURNAL*, 17, 593 (1895)). The powers were 330 and 440 (equivalent to about 500 and 660 Lintner) and nitrogen contents (dry, ash-free basis) 15.9 and 16.0%, respectively, thus closely resembling Osborne's Preparation 15 (*Ibid.*, p. 598) from his Precipitate IV.

Preparation 125 was intended as a repetition of 124 and gave products of practically the same power but the yield of the second fraction was too small to permit accurate determination of nitrogen.

We are greatly indebted to the Carnegie Institution of Washington for grants in aid of this investigation.

LABORATORY OF FOOD CHEMISTRY, COLUMBIA UNIVERSITY,
NEW YORK CITY.

¹ Here, as in all cases, the diastatic power is expressed on the basis of air-dry material.

STUDIES ON ENZYME ACTION. XIII. THE LIPASE OF SOY BEANS.

BY K. GEORGE FALK.

Received January 7, 1915.

In continuation of the study of lipolytic activities reported in previous papers,¹ the results obtained in the study of the lipase of soy beans by methods similar to those used in the study of castor bean and duodenal lipases will be given.

Two preparations were used in this work: S.B. I; yellow soy beans, ground, extracted with ether in a Soxhlet apparatus, dried in air, and ground to pass through a 40-mesh sifter; S.B. II; the shells of the soy beans were removed by hand, the kernels ground, extracted with ether, air dried, and ground to pass through a 40-mesh-sifter.

To test the activities of the preparations, the weighed substance with the stated amount of water or of solution in a stoppered Erlenmeyer flask was placed in the incubator at 38–40° with the ester (either 1 cc. ethyl butyrate, denoted by EtBu, or 0.5 cc. glyceryl triacetate, denoted by Triac.) for 24 hours, and then titrated with approximately 0.1 *N* standard NaOH solution, with phenolphthalein as indicator. The final results, corrected for blanks, alone are given, and represent the number of cc. of 0.1 *N* acid formed under the conditions stated by the action of the lipase upon the ester. Toluene was used throughout as antiseptic.

The effect of heating and of drying on the activity of S.B. II was studied and the results are given in Table I. The first column indicates the treatment before testing; the second, the amount of substance used; the third, the loss in weight in grams; the fourth, the percentage loss; and the fifth and sixth the activities of 0.18 g. portions of the treated material in 25 cc. water, except for the first row where the activities of 0.2 g. portions of untreated material are given.

¹ THIS JOURNAL, 34, 735 (1912); 35, 210, 601, 616, 1897 (1913); 36, 1047, 1904 (1914); 37, 217 (1915).

The loss in weight due to drying did not decrease the activity, but an almost equal loss in weight due to heat decreased the activity 50%. Similar results were obtained with castor beans except that with them almost the whole of the activity was lost in heating.

Series of experiments were made in which the activity of both soy bean preparations was tested in solutions containing salts and alcohols of different concentrations. In each test 25 cc. of solution and 0.2 g. of preparation were used. The action on ethyl butyrate in water alone is small, so that practically no effect was noticeable due to added substance in most cases. Only in 0.1 *N* sodium fluoride and in the most concentrated sodium chloride solutions were marked retardations observed. Table II shows the results obtained with triacetin in salt solutions of the indicated concentrations.

0.2	1.95	0.5	2.26	2.31
0.5	1.39	1.0	1.90

The S.B. II preparation showed a greater activity than did the S.B. I preparation in almost every case. With sodium chloride, the activity increased with increase in concentration of the salt until the concentration 0.1 *N* was reached, and then decreased with more salt. With sodium bromide, a similar maximum activity was observed at 0.1 *N*. Sodium fluoride exerted a very marked retardation. Magnesium sulfate accelerated in dilute (0.01 *M* to 0.05 *M*), and retarded in more concentrated solution. Manganous sulfate accelerated strongly. Methyl alcohol and ethyl alcohol exerted no appreciable effect in dilute solutions (up to about 0.1–0.2 *M*); at greater concentrations, retardation was observed. This was greater with ethyl alcohol than with methyl alcohol. On the whole, these lipase actions towards triacetin in solutions of different substances resemble very closely those previously reported with the

castor bean and duodenal lipases, so that similarities in their chemical nature may fairly be deduced from the similarities in their chemical behavior under various conditions.

Some extraction experiments were made with S.B. I.¹ 0.2 g. of preparation was treated with 25 cc. water for the lengths of time indicated, filtered through asbestos with suction, the activities of the filtrates tested and the residues either extracted again or tested for lipolytic action. The results are given in Table III.

TABLE III.—ACTION OF AQUEOUS EXTRACTS OF SOY BEAN PREPARATION (S.B. I) ON (a) ETHYL BUTYRATE AND (b) TRIACETIN (24-HOUR TESTS).

	Filtrate.	Residue (H ₂ O). ²	Total.
(a) Direct tests, not filtered.....	0.45
One minute extraction.....	0.13	0.31	0.44
24 hrs. extraction.....	0.17	0.15	0.32
Second successive 24 hrs. extraction.....	0.02	0.17	0.36
(b) Direct tests, not filtered.....	2.70
One minute extraction.....	1.07	1.29	2.36
24 hrs. extraction.....	1.45	0.93	2.38
Second successive 24 hrs. extraction.....	0.24	0.87	2.56

The fractional parts of the two types of activity extracted by water did not differ much. This, taken with the preceding results, indicates that very little, if any, esterase (active toward ethyl butyrate) is present in the soy beans, but that considerable quantities of lipase (active toward triacetin) are. The amounts of the latter which were extracted by water ranged from 45% for the one minute extractions to 66% for two successive 24 hrs. extractions. These results differ markedly from the results obtained with castor bean preparations, which showed two types of action which could be separated by their different solubilities.

The filtrates obtained in these extractions were somewhat cloudy as a rule. On dialyzing these for 24 hrs. in collodion bags against running water, the cloudiness was increased with the separation of small amounts of precipitate. These dialyzed solutions on repeated filtration through hardened filters gave perfectly clear solutions which showed very nearly the same activity toward triacetin as the original undialyzed extracts. The solubility of the lipase of soy beans to form a clear solution in water is in marked contrast to the properties of the castor bean enzymes. There the esterase was found to be soluble and the lipase insoluble in water. The addition of three volumes acetone to the soy bean lipase solution precipitated a light gray powder, which, after grinding with fresh acetone and drying in a vacuum desiccator showed no activity, and on analysis gave a nitrogen content (Kjeldahl) of 14.0%.

¹ Cf. IX Paper, THIS JOURNAL, 35, 1904 (1913), for similar experiments with the castor bean lipase preparation.

² Residue treated with 25 cc. water and the activity tested.

A number of extraction experiments were made with sodium chloride solutions of different concentrations. In these, 0.5 g. S.B. II were extracted with 60 cc. solution for 24 hrs. at room temperature, filtered through asbestos, the filtrates dialyzed for 20 hrs. in collodion bags against running water, and then tested for 24 hrs. The results were corrected for purposes of comparison to show the activities obtained from 25 cc. of original undialyzed extract. Toward ethyl butyrate practically no activity was shown by the extracts. Toward triacetin the following mean results were obtained:

Conc. NaCl solution.....	0	0.5 M	1.0 M	1.5 M	2.0 M	2.5 M	3.0 M	Saturated
Activity found (Triac.)....	1.13	1.48	1.52	2.11	1.10	1.06	1.07	0.59

A marked maximum is observable for the 1.5 M solution; that is to say, this solution extracted most active lipase, almost twice as much as water. The behavior of these salt solutions toward soy beans is strikingly similar to their behavior toward castor beans.¹ In both cases, the maximum quantity of lipase is extracted by 1.5 M sodium chloride solution (about 9% solution). This concentration of salt solution is also very near that generally used in extracting proteins from seeds.² The residues from extracting the soy beans with the different salt solutions on a second extraction and filtration with salt solutions of the same strength as before, showed very little activity in the filtrates.

Some analyses of the S.B. II preparation may be of interest. The methods used were the same as those previously described. The substance, dried in a vacuum desiccator over phosphorus pentoxide, showed a nitrogen content of 8.9%, ash 4.46%, P_2O_5 1.41%, CaO 0.31%, and MgO 0.66%. The forms of combination of the nitrogen in the preparation, according to Van Slyke's method, were the following, expressed as percentages of the total nitrogen: Ammonia, 10.6; melanine, 4.3; arginine, 16.0; cystine, 3.7; histidine, 5.7; lysine, 6.5; amino nitrogen in filtrate, 47.1; non-amino nitrogen in filtrate, 3.3; total, 97.2%. The preparation gave strong tests for tyrosine (Folin reagent) and for carbohydrates (Molisch test).

The writer wishes to thank Mr. K. Sugiura for his aid, especially in making the analyses, and Mr. M. Erenstoff for his help in much of the experimental work.

Summary.

The lipolytic properties of soy beans were studied by the methods used in the similar studies of castor beans and of duodenal contents.

A comparison of some of the properties of these hydrolytic enzymes showed the following relations:

Soy beans contain a lipase active toward triacetin (and therefore presumably toward fats), somewhat soluble in water, with a maximum solubility in 1.5 N sodium chloride solution. Castor beans contain an esterase soluble in water and a lipase insoluble in water and soluble in sodium

¹ XII Paper of this series, THIS JOURNAL, 37, 217 (1915).

² Cf. Osborne, "The Vegetable Proteins," 1909, p. 16.

chloride solution with a maximum solubility at the concentration 1.5 *N*. Duodenal contents contain an esterase and a lipase, the former predominating in the intestinal juice, the latter in the pancreatic juice and bile.

Marked similarities in the action of neutral salts and alcohols are shown by the lipases from different sources.

The action of heat and of drying on the soy bean lipase was found to be similar to their action on castor bean lipase and esterase.

The analyses of the soy bean lipase preparations showed no marked differences in comparison with the analyses of the castor bean preparations.

ENZYMES OF THE CENTRAL NERVOUS SYSTEM.

By H. M. ENGLISH AND C. G. MACARTHUR.

Received January 13, 1915.

The enzymes of the brain and nerves have not been investigated as thoroughly as those of most other tissues. This is rather surprising when one considers the supreme importance of the nervous system. Most of the previous data on brain enzymes has been obtained as part of other investigations, the enzymes of the nervous system having been considered only incidentally. The work here presented had for its object the beginning of a more systematic study of the enzymes of nervous tissue and a somewhat more detailed study of the most important ones.

Preparation of Extracts.

For the larger part of this work fresh sheep brains, packed in ice soon after removal from the animals and expressed directly from Chicago, were used. The membranes and blood vessels were removed and the brain divided into cerebrum, cerebellum, medulla, mid-brain, and, in some cases, corpus callosum. These divisions were minced separately in a meat grinder, then ground to a fine state in a mortar, with either toluol or oil of mustard as a preservative, usually the latter, and extracted with water 0.2% HCl, 0.9% NaCl, 0.5% Na₂CO₃, chloroform water or glycerin. In each case 1 cc. of the liquid was used for each gram of brain tissue.

As a check on this method and also for the sake of comparison with other methods the following procedures were carried out:

The ground tissue (with or without preservative) was spread in thin layers on watch glasses and placed in large desiccators. The glasses were surrounded by a cylindrical screen outside of which calcium chloride was placed. The desiccator was placed in a jar and packed with ice and salt. When the tissue was frozen the desiccator was evacuated. By frequent renewing of the vacuum the tissue could be dried in one to two days. A part of this dried material was tested directly while the rest was ex-

tracted twice with benzene by continual shaking in a mechanical shaker. After this treatment a light powdery substance was left. When this was used for enzyme study an amount of extractive and water was used that so compared with that used on the moist tissue that the enzyme content should be comparable.

The chief objection to this ideal method is that it cannot easily be used on large amounts of material and it is somewhat slow. A quicker method is to spread the ground tissue and preservative in very thin layers on glass plates. These plates were placed in a specially constructed box through which a current of air was drawn by an electric fan. By frequent turning, the tissue can be dried in ten to fifteen hours. Some of this air-dried material was treated with benzene to remove the lipoids, as had been done with the tissue dried by the freezing method.

In making the extractions the tissue was placed in cheesecloth sacks and suspended in wide mouth bottles containing the extractives. More preservative was added and the bottles stoppered. These were usually left at room temperature for from three to seven days. The sacks were then lifted out of the extractives, allowed to drain for a few hours and discarded. The extracts were placed in a refrigerator and used as soon as possible.

The test solutions were ordinarily prepared as follows: 4 cc. of substrate were added to 10 cc. of extract and 100 cc. of water. The solution was mixed thoroughly and exactly 50 cc. placed in each of two 150 cc. flasks. One of these was boiled to destroy the enzymes, and both were then placed for 48 hrs. in an air thermostat kept at 37.5°. When a large number of tests were to be run on the same substrate, a solution was made containing the right proportions of substrate and water and 100 cc. of this solution used for 10 cc. of extract. In the case of insoluble substrates like olive oil and ethyl butyrate, emulsions of these were produced by making the liquids slightly alkaline and thoroughly shaking. When activators were used they were always added to the enzymes before the substrate had been put in.¹ After 48 hrs. in the thermostat the amount of activity was determined. For the action on fats, fat-like compounds and salol, direct titration was made with 0.1 *N* sodium hydroxide using phenolphthalein as indicator. For the action on proteins the formaldehyde method was used. With amylases the amount of activity was estimated by the copper hydroxide reduction test.

Results and Discussion. 1. Lipase.

Extractives for Lipase.—It was desirous at the outset to find the best method of extracting the enzymes, or at least a good method. It is obvious that the method which might prove best for one enzyme might be

¹ Rosenheim and Shaw-Mackenzie, *J. Physiol.*, 40, Pro. VIII (1910).

a very poor method for extracting others. Active lipolytic extracts¹ were obtained with all the solvents used.

Two such series after extracting for seven days gave the following results when acting on a mixture of equal amounts of monoacetin and mono-butylin:

TABLE I.

Tissue.	Extractive.	0.1 N NaOH required for neutralization.	
		Cc.	Cc.
Fresh cerebrum.....	H ₂ O	1.34	0.85
Fresh cerebrum.....	0.2% HCl	0.13	0.24
Fresh cerebrum.....	0.9% NaCl	1.21	0.82
Fresh cerebrum.....	0.5% Na ₂ CO ₃	1.30	0.70
Fresh cerebrum.....	CHCl ₃ water	1.34	1.13
Fresh cerebrum.....	Glycerin	(3.75) ²	0.78
Frozen cerebrum, no preservative....	H ₂ O	1.94	..
Frozen cerebrum, no preservative....	Glycerin	(0.11)	..
Frozen cerebrum with preservative....	H ₂ O	2.31	..
Air dried cerebrum.....	H ₂ O	1.37	..
Air dried cerebrum (ext. with benzene)	H ₂ O	2.71	..

Another series of extractions was run on the cerebrum with a view of finding out the rate of extraction of the various liquids. In this series ethyl butyrate was used as a substrate.

TABLE II.

Tissue.	Extractive.	0.1 N NaOH required for neutralization after extracting for			
		5 days. Cc.	7 days. Cc.	9 days. Cc.	12 days. Cc.
Cerebrum.....	H ₂ O	0.30	1.25	1.18	1.83
Cerebrum.....	0.2% HCl	0.19	(0.85)	0.50	0.57
Cerebrum.....	0.9% NaCl	0.38	0.60	1.10	1.19
Cerebrum.....	0.5% Na ₂ CO ₃	0.45	0.64	1.30	1.18
Cerebrum.....	Glycerin	0.15	0.14	0.37	0.50

The results of these experiments indicate that water, sodium chloride, sodium carbonate and chloroform water are about equal as extractives. The acid extractive seems to be less well suited for extracting the lipase, since the values for its activity are considerably lower. Probably the difference in the results with the various extracts of glycerin is due partly to the substrate used and partly to the amount of water present with the glycerin. It will be noticed that with the frozen dried tissue the amount of activity, when extracted with glycerin (no water being present), was

¹ J. H. Coriat, *Am. J. Physiol.*, 12, 353 (1904); A. Pagenstecher, *Biochem. Z.*, 18, 285 (1909); A. Wroblewski, *Compt. rend.*, 152, 1334 (1911); L. Buetow, *Biochem. Z.*, 54, 40 (1913).

² The values in parenthesis are not considered comparable and are obviously inconsistent with the other data given. Explanations for these apparent discrepancies will be given wherever possible.

very small. The value 0.78 agrees best with other data on the glycerin water extracts and is very likely the most reliable one for comparison.

The drying method in general seems to give slightly better results than the direct extraction method. The air-dried tissue extracted immediately with water gave about the same activity as the fresh tissue extracted with water, the figures being 1.34 and 1.37. The air-dried tissue which had been extracted with benzene gave the highest activity of any of the dried portions. Just why this is true is not clear, unless the lipoids exert an inhibiting or protecting influence upon the lipase.

With the frozen tissue extracted with water greater activity was obtained than with fresh tissue extracts. The tissue frozen without a preservative gave a little less activity than that in which a preservative was used. (A preservative was used in both cases when the extractions were made.) It is doubtful if these figures are of any great significance other than the fact that the preservative, which was oil of mustard in these series of experiments, exerted no inhibiting influence upon the enzyme.

Best Medium for Lipase.—With regard to the nature of the medium in which the lipase acts best, experiments show that a medium of slight acidity is best suited to its activity. In testing out this point, alkaline extracts were used in two different experiments. In one flask the solution was left alkaline, while in the other a slight acidity was produced. Similarly acid extracts were tried out in both acid and alkaline media. With a mixture of monoacetin and monobutylin, the following results were obtained:

TABLE III.

	Cc. 0.1 N NaOH.	
	I.	II.
0.5% Na_2CO_3 extract; slightly acid.....	1.15	0.70
0.5% Na_2CO_3 extract; slightly alkaline.....	0.79	0.37
0.2% HCl extract; slightly acid.....	0.33	0.24
0.2% HCl extract; slightly alkaline.....	0.17	0.18

The alkaline extract as shown before is more active than the acid, but larger activity is produced by the alkaline extract if the medium is made slightly acid at the start. The acid extract likewise is better suited to an acid medium.

Substrates.—The lipase found in different portions of the brain possesses the power of acting on many substrates. Some results obtained with different extracts are given in Table IV.

There is no basis for comparison of the various extracts of this table since the conditions under which the different experiments were carried on were varied.

The best substrates are triacetin and monoacetin. Tributyrin, monobutylin and ethyl butyrate were acted upon quite readily. Lard, tallow

and butter may owe their lesser activity to the fact that they do not go into solution and at best form only finely divided particles when ground with water in a mortar or thoroughly shaken with water. Cephalin and lecithin were affected to the same degree as olive oil. No specificity of action was noticed with brain lipase other than the one of rate of hydrolysis of the various substrates.

TABLE IV.

Cc. of 0.1 *N* NaOH required for neutralization.

Substrate.	Water ext. of cerebrum.		Water ext. of medulla.	Na ₂ CO ₃ ext. of cerebrum.
Triacetin.....	0.56	0.36
Monoacetin.....	1.37	2.80	..	0.29
Tributylin.....	0.24
Monobutylin.....	0.84	2.40	0.25	0.08
Ethyl butyrate.....	..	2.23	0.15	0.13
Olive oil.....	0.15	0.26	0.29	(0.56)
Lard (hog).....	0.19
Tallow (beef).....	0.16
Butter.....	0.17
Lecithin.....	0.25	0.19
Cephalin.....	0.20	0.27	..	0.23

Conditions Best Suited for Action.—Since the activity at any one time depends upon a large number of conditions it was decided to run a set of experiments in which each condition in succession would be varied while the others would be constant. The different conditions varied were the amount of extract, the amount of substrate, the substance used as an activator, the amount of dilution, and the time during which the enzyme was allowed to act. The substrate used was ethyl butyrate.

In preparing the solutions in these experiments, a considerable amount of each proportion of ethyl butyrate and water desired was made slightly alkaline and thoroughly emulsified. When used, the emulsion was thoroughly mixed with the extract and two equal amounts of the mixture taken, one for a check and the other for enzyme activity. In the cases where an activator was used, it was always mixed with the extract before either was added to the substrate.¹ The figures in the results represent the cc. of 0.1 *N* NaOH required to neutralize the difference between the check and normal flasks.

Where one set of conditions was varied the remaining conditions were kept under circumstances found favorable in previous experiments. Thus, when the amount of extract was varied with the amount of substrate, no activator was used, the dilution was 50 cc. and the time two days. When the amount of dilution was varied with the time, 5 cc. of extract were used, 0.2 cc. of substrate, and no activator.

The results indicate clearly that the amount of activity of the brain

lipase on ethyl butyrate varies directly with the amount of enzyme, and the amount of substrate, used. In every case with the exception of one, the activity was increased where either one of these factors was enlarged. The one exception is the case of the variation of the amount of extract with sodium glycocholate as an activator. Here the greatest activity, contrary to expectations, was obtained in the flask containing 5 cc. of extract and not in the one containing 15 cc.

In varying the dilution a peculiar result was obtained. Activity was, as a rule, greater in both the smallest and largest dilutions than it was in the medium dilution. This may be accounted for by supposing that water inhibits the enzyme, but that the larger the dilution the oftener the interacting molecules collide.

In the flasks in which the time of action of the enzyme was varied, the amount of activity gradually increased with the time. With one exception, there was no evidence of the end point having been reached even at the conclusion of the sixth day.

With the activators the results were less definite. The amount of phosphates used was 2.5 cc. of a 1% solution of equal amounts of the mono-basic and dibasic phosphates of sodium. 2.5 cc. of a 0.02 molar solution of sodium glycocholate, and 2.5 cc. of a 0.25% solution of saponin were used. The greatest activity was obtained with the phosphates and the least with the sodium glycocholate, although the activity was not increased markedly in any case. As is to be noticed from the table, it is doubtful if the activity was increased at all with sodium glycocholate. If any conclusion can be drawn it would seem to be that sodium glycocholate does not markedly increase the activity of brain lipase on ethyl butyrate under any of the conditions under which it was tested.

With saponin slightly higher activity was obtained, but this was not much above the normal activity. The three values obtained for saponin when the amount of extract was varied, were 0.20, 0.34, and 0.60. The three corresponding normal values were 0.28, 0.37, and 0.64. When the amount of substrate was varied, the three values were 0.15, 0.34, and 0.68, while the normal values were 0.26, 0.37, and 0.53. It would seem from these latter results that saponin has more influence in larger amounts of substrate, although the differences are not sufficient to guarantee this conclusion. The values obtained for the activity of saponin under different dilutions do not differ to any appreciable extent from the normal values. With the different lengths of time the values are also close to normal.

The values obtained with a mixture of mono- and dibasic phosphates acting on different amounts of enzyme are approximately equal to the normal values, and the amounts of activity obtained with the two smaller concentrations of substrate are not far from the normal values, but the value obtained with phosphates acting on a large amount of substrate is

considerably higher than the corresponding normal value, the figures being 0.92 and 0.53, respectively. This result would seem to indicate that phosphates, like saponin, increase the activity in large concentrations of the substrate. The results obtained for different lengths of time through which the enzyme was allowed to act are not markedly different from the values obtained when no phosphates were present.

In regard to the influence of activators on the action of the enzyme, it should be stated that larger increases in activity were obtained when monoacetin was used as a substrate with a water extract of the cerebrum. Values obtained under comparable conditions are as follows:

TABLE VI.

	Cc. 0.1 <i>N</i> NaOH.
5 cc. ext., 0.2 cc. monoacetin.....	2.87
5 cc. ext., 0.2 cc. monoacetin, 2.5 cc. 0.02 <i>M</i> sodium glycocholate.....	3.05
5 cc. ext., 0.2 cc. monoacetin, 2.5 cc. 0.25% saponin sol.....	3.11
5 cc. ext., 0.2 cc. monoacetin, 2.5 cc. 1.0% phosphate sol.....	3.63

From these results it will be seen that sodium glycocholate and saponin slightly increased the activity of the lipase, while phosphates increase it markedly. Previous investigators¹ have shown that saponin and sodium glycocholate considerably increase the activity of the pancreatic lipase. The accelerating action of phosphates on the brain lipase has also been reported.²

Lipase in the Different Divisions of the Brain.—The different divisions of the brain when kept under conditions as nearly as possible identical and extracted with water, gave the following activity:

TABLE VII.

	Cc. of 0.1 <i>N</i> NaOH.			Cc. of 0.1 <i>N</i> NaOH.	
	I.	II.		I.	II.
Cerebrum.....	1.34	1.25	Medulla.....	0.45	0.36
Cerebellum.....	(2.10)	0.87	Corpus callosum.....	0.61	0.56
Mid-brain.....	1.25	1.23			

These results indicate clearly that the gray matter is more active from a lipolytic standpoint than the white. The corpus callosum which is made up almost entirely of white matter would naturally be expected to give the lowest activity, but although it was obtained as free as possible from gray matter, it nevertheless showed greater activity than the medulla. The activities of the two cerebrums were about equal, while the activity of one cerebellum was higher and the other lower than those of the cerebrum and mid-brain. Very probably the lower value is nearly correct. Since the mid-brain contains large nuclei of gray matter, it seems probable that the greater part of its activity depends upon these. The medulla,

¹ Rosenheim and Shaw-Mackenzie, *J. Physiol.*, 40, Pro. VIII (1910).

² A. Wroblewski, *Compt. rend.*, 152, 1334 (1911).

which is very similar to the mid-brain structurally but lacks the large nuclei, showed considerably less activity.

Lipase in Brains of Different Animals.—Human, beef, sheep, and dog brains have been tested for lipolytic activity and all found to be active. No experiments were run with extracts from each source under strictly comparable conditions, so that an exact estimate could not be made of the relative quantities of lipase contained in the brain from the different sources. Figures which were obtained from extracts of the different brains acting on triacetin are given below:

TABLE VIII.

	Cc. 0.1 N NaOH.		Cc. 0.1 N NaOH.
Human cerebrum.....	3.50	Sheep cerebrum.....	4.31
Beef cerebrum.....	4.50	Dog cerebrum.....	3.60

While these values do not give an accurate idea of the lipase content of the different brains, they nevertheless show that all have the ability to split triacetin to about the same extent.

2. Proteolytic Enzymes.

The presence of a proteolytic enzyme¹ in nerve tissue has been indicated by the action of tissue extracts on various proteins. Time did not permit of an extensive study of this enzyme, or enzymes; but it has been found to attack several different proteins. A glycerin-water extract of the cerebrum prepared by the freezing method gave the following results when the resulting solution was tested for amino acids by the formaldehyde method:²

TABLE IX.

	Cc. 0.1 N Ba(OH) ₂ .		Cc. 0.1 N Ba(OH) ₂ .
Egg albumen.....	0.2	Witte's peptone.....	0.95
Gelatin.....	1.92	Nuclein.....	0.69
Casein.....	0.98		

The splitting of Witte's peptone was expected because of the presence of erepsin in most of the tissues so far studied; but it would seem that erepsin alone would hardly account for the large action on the more complex proteins, and it is probable that a pepsin or trypsin-like enzyme, or both, are present throughout the brain as well as in the hypophysis where both have been found.³

The proteolytic action of brain extracts on Witte's peptone takes place most rapidly in alkaline medium.

TABLE X.

Witte's peptone, slightly acid medium.....	0.50 cc. 0.1 N Ba(OH) ₂
Witte's peptone, slightly alkaline medium.....	1.92 cc. 0.1 N Ba(OH) ₂

¹ Kutscher and Lohman, *Z. physiol. Chem.*, **39**, 313 (1903); H. M. Vernon, *J. Physiol.*, **32**, 33 (1904); A. Wroblewski, *Compt. rend.*, **152**, 1334 (1911); L. Buetow, *Biochem. Z.*, **54**, 40 (1913).

² S. P. L. Sorensen, *Biochem. Z.*, **7**, 45 (1908).

³ L. Buetow, *Biochem. Z.*, **54**, 40 (1913).

Tests of the various kinds of extracts on Witte's peptone gave the following amounts of activity, 5 cc. of extract and 5 cc. of a saturated solution of peptone being used in each case:

TABLE XI.

	0.1 N Ba(OH) ₂ .		0.1 N Ba(OH) ₂ .
Water.....	0.15	0.5% Na ₂ CO ₃	0.25
0.2% HCl.....	0.12	CHCl ₃ H ₂ O.....	0.21
0.9% NaCl.....	0.16	C ₃ H ₅ (OH) ₃	0.45

Here again the acid extract is shown to form a poor medium for the action of the protease. The sodium carbonate extract is better, but the highest activity was obtained with the glycerin extract and the results of a previous table show further that that extract was effective on other proteins as well as on Witte's peptone (Table IX).

3. Other Brain Enzymes.

In searching for *rennin*, negative readings were obtained by the use of the metacasein test.

The *amylase* content of brain tissue seems to be very slight.¹ No action at all could be detected in tests on starch, glycogen, amygdalin, sucrose, maltose, lactose, and dextrose. Dextrin, however, was slightly hydrolyzed. A solution of *dextrin* in which the enzyme had been allowed to act, gave a slight copper hydroxide test for the presence of a reducing sugar, while the check solution gave no test. The glucosides, arbutin and salol² are hydrolyzed by water extracts of the brain. A solution of *arbutin* after being acted upon by the enzyme gave a strong copper hydroxide test, while in the boiled check no copper was reduced.

With *salol* the following results were obtained by direct titration of the solutions:

TABLE XII.

	Cc. 0.1 N NaOH.
Unboiled flask containing enzyme and salol.....	1.52
Boiled flask containing enzyme and salol.....	0.76
Difference = enzyme activity.....	0.76

Since the cerebroside, cerebrin, contains a galactose grouping, it was thought possible that this might be split off by the *amylase*, but in several tests made on a mixture of cerebrosides no reduction of copper was obtained.

Catalase can easily be proved present in brain tissue. A water extract of the cerebrum was divided into two portions, one of which was boiled. Equal amounts of these two solutions were then mixed with equal amounts

¹ A. Wroblewski, *Compt. rend.*, **152**, 1334 (1911); Wohlgenuth and Szecsi, *Z. Neurol. Psych.*, **13**, 454 (1913); L. Buetow, *Biochem. Z.*, **54**, 40 (1913); V. Kafka, *Zentr. Biochem. Biophys.*, **14**, 294 (1913).

² A. Wroblewski, *Compt. rend.*, **152**, 1334 (1911).

of hydrogen peroxide, placed in fermentation tubes and set in the thermostat. At the end of two hours the tube containing unboiled solution had in it from four to eight cc. of gas which proved to be oxygen, while the boiled check had produced no gas. The results show that the decomposition of hydrogen peroxide, which takes place at a slow rate under normal conditions, is greatly accelerated by the presence of the brain extract, and since such acceleration is not produced by boiled extract, it must be due to some thermolabile compound contained in the extract.

Tests were made for other enzymes and negative results obtained.

*Peroxidase*¹ was tested for by the guaiac test, in which guaiac, in the presence of hydrogen peroxide, is turned blue if the enzyme is present. No blue coloration was obtained. Tests for *oxidase* also resulted in the negative. A solution of alpha naphthol was not changed to a blue color in the presence of a tissue extract as is the case when certain oxidases are present;² formaldehyde was not oxidized to formic acid; and xanthin and hypoxanthin were not converted into uric acid. It is probable, since both of these enzymes have been reported by several investigators, that conditions were not exactly favorable for their detection or the specific tests were not used. It has been shown that glucose³ and other powerful reducing substances, haemoglobin,⁴ and protein interfere with different oxidase tests.

Reductase could not be demonstrated by the methylene-blue test which depends upon the decoloration of a dilute solution of methylene blue by formaldehyde. Here again the conditions may have been unfavorable for the action of the enzyme.

Guanase, which transforms guanine into xanthine, and *urease*,⁵ which produces carbon dioxide and water from urea, could not be detected in the brain extracts. It is probable that both of these, if present at all, are present in such small quantities as to be undetectable by the methods used.

Summary.

1. The brain contains a lipase, erepsin, an amylase, a catalase, enzymes which decompose arbutin and salol, and probably a pepsin or trypsin-like enzyme, or both.
2. The lipase and proteases are best extracted by a mixture of glycerin and water or by water.
3. Extracts of tissue, dried either by the freezing or air-current method, showed greater activity than extracts of fresh tissue.
4. The highest activity was obtained from tissue extracted after drying with benzene to remove the lipoids.

⁴ Czylharz and v. Furth, *Hofmeister's Beitr.*, 10, 358 (1907).

⁵ L. Buetow, *Biochem. Z.*, 54, 40 (1913).

5. Triacetin and monoacetin form the best substrates for the action of the lipase. Lecithin and cephalin are also acted upon by it.

6. The amount of activity of the lipase, as has been shown for other enzymes, is increased directly with the amount of enzyme, the amount of substrate, and the time during which the enzyme is allowed to act.

7. The amount of activity of the lipase is increased by the presence of sodium glycocholate, saponin, or a mixture of the mono- and dibasic phosphates of sodium.

8. The lipase acts best in a slightly acid medium, the erepsin in an alkaline medium.

9. In general, the gray matter is more active than the white. Higher activity was obtained with extracts of the cerebrum, cerebellum, or mid-brain than with extracts of the medulla, or corpus callosum.

10. Human, beef, sheep, and dog brains all contain similar amounts of lipase.

11. Negative results were obtained in tests for peroxidase, oxidase, reductase, guanase, urease, and rennin.

URBANA, ILL.

NOTE.

The Origin of Petroleum.—It has been some time since I suspended publication on various lines of study on petroleum and its constituents, and it therefore seems necessary, to retain this field, that a brief mention be made of the present condition of my work, that others may not with perfect propriety take up some parts of it which I now have in progress. I am now using the information gained during the last thirty years in aid of further examination of the constituents of petroleum with especial reference to their original formation. It appears that twenty or more crude oils including those of Russia, South America, Texas, Canada and Louisiana contain the identical series of nitrogen compounds that were formerly described as present in California petroleum. These compounds are not pyridine as was formerly made plain in the paper on the California oils. This subject I have now in hand, together with a method for the determination of the small proportions of nitrogen contained in crude oils.

I am also carrying on a study of the action of sulfur on the constituents of petroleum, the series C_nH_{2n+2} , C_nH_{2n} , C_nH_{2n-2} , and C_nH_{2n-4} . Hydrogen is readily removed at temperatures near 150° with the formation of heavier oils, and at the same time with the formation of sulfur derivatives of the hydrocarbons. It is proposed to include in these changes the hydrocarbons all the way to the asphalts. I also have in hand series of hydrocarbons obtained by the distillation of coal *in vacuo*, and of gilsonite

in vacuo; the latter yields about 50% of its weight in distillates. These have been fractioned *in vacuo* and await further examination.

NEW BOOKS.

Essays and Addresses. By the late JAMES CAMPBELL BROWN, D.Sc. (Lond.), LL.D. (Abdn.), Professor of Chemistry in the University of Liverpool. With a portrait and twenty-two illustrations. J. & A. Churchill: London, 1914. vii + 208 pp. Price, \$2.00 net.

This book has been published in response to the request of many of the former pupils and friends of Dr. Campbell Brown for copies of addresses, either never published, or at present out of print. Five of the twelve numbers were delivered before the student chemical society of the University College, Liverpool, and two others before a joint meeting of the societies of the same college, while three were delivered before the Liverpool Section of the Society of Chemical Industry, two of them being addresses as Chairman of the Section.

Perhaps the most interesting papers are the translation of an autobiographical sketch of Liebig, originally published in the *Deutsche Rundschau*, and a reminiscent sketch of Hofmann. Speaking of the long hours kept by students, assistants, and Hofmann himself, in the little group at the Royal College of Chemistry, he adds: "That is the kind of work that tells. An eight-hour day may be all very well for working men who have no ambition and who are content with daily bread (and beer); but a gentleman has to work much harder." Other essays on technical education and chemistry as a profession, discuss perennial problems in an interesting manner, while the papers on Ethics of Chemical Manufacture, and a French View of German Industries, are far from being out of date. The only strictly scientific paper is one on Aquiculture: a Study of Deposits in Pipes.

The book as a whole is pleasant reading, and will be especially welcome to the old students and many friends of the genial Liverpool professor.

JAS. LEWIS HOWE.

Zur Lehre von den Zuständen der Materie. By P. P. VON WEIMARN. Vol. I, 183 pp. Vol. II, 100 photographic illustrations. Theodor Steinkopff, Dresden & Leipzig. Price M. 7 unbound, M. 9 bound.

This is a reproduction of the author's articles in the *Kolloid Zeitschrift*, 1908-9, without much of the theoretical matter then published.

Proceeding on the idea that every insoluble substance is capable of assuming the colloidal state by sufficient subdivision, he devotes much of the experimental work to the forms of barium sulfate. This and

aluminum hydroxide are the basis of a thorough study of the conditions of matter in the colloidal solution and solute states, and the author has carried his studies very far beyond the work of others on the general subject. His photographs show barium sulfate as perfectly colloidal, resembling gelatin, and also in all stages of crystalline growth. He supports the theory that there are no really amorphous substances and that every substance may be made to assume either amorphous or crystalline states at will.

To produce the amorphous colloidal state, the substance must be produced under conditions of very low solubility.

He ascribes to the substance a coefficient of form of precipitate (N). This determining factor he places proportional to the concentration of the four compounds in equilibrium in the metathesis which produced it, and to the quantity of the precipitating substance which must ultimately separate from the solution in granular phase, inversely proportional to the solubility of this compound and proportional to the viscosity of the solution. That is, the coefficient is the product of these factors.

The two volumes contain much interesting work. The second is devoted entirely to microphotographs. The experimental work is largely original and the whole forms an interesting suggestive addition to the more specific subject of colloids rather than to the title, "Zustand der Materie."

W. R. WHITNEY.

Handbuch der Arbeitsmethoden in der anorganischen Chemie. Edited by DR. ARTHUR STÄHLER, Privatdozent in the University of Berlin. Vol. III, first half. Veit & Company, Leipzig, 1913. 682 pages, 354 fig. Price, bound, 25 marks.

Vol. I, published in 1912, 786 pages, 1064 fig., bound 28 marks, treated of the laboratory and its equipment—mechanical operations. Vol. II, not yet published, is to be devoted to physical and chemical processes. Vols. IV and V will treat of descriptive inorganic chemistry. Volume III, of which this is the first half, is devoted to physico-chemical measurements. The topics treated in this part with their authors are as follows: Vapor Density, Osmotic Pressure, Viscosity, Diffusion, Conduction of Heat and Specific Heat (Eucken); Weight, Volume and Density (Fellgentraeger); Surface Tension (Freundlich); Density of Gases (Guye); Metallurgy (Gerens and Ruer); Compressibility and Thermal Expansion (Heuse); Solubility of Gases (Just); Critical Constants (Klemensiewicz); Boiling and Subliming Points (Krafft); Compressibility and Thermostats (Richards); Molecular Weights in Solution (Sieverts); Calorimetry and Heat of Reaction (Steinwehr); Solubility and Adsorption (Thiel); Melting Points (v. Wartenberg).

As this list indicates the plan of the entire work involves the coöperation of a brilliant corps of co-editors, including in addition to those whose names occur above, many well-known chemists, each writing on one or more subjects in which, as a rule, he himself has been an active investiga-

tor. In some chapters, as for example, that on weighing, matters of real interest to the specialist are preceded by a detailed discussion of the most elementary topics. In other chapters, notably that dealing with the determination of molecular weights by the boiling point method, long descriptions of primitive forms of apparatus are given, the inclusion of which might be the subject of criticism were it not for the fact that the latest improved forms are also described, thus giving the reader the history of the evolution of the subject.

The result is the production of an exhaustive as well as an authoritative treatise that must become indispensable to all advanced workers in the field of general and physical chemistry. HERBERT N. MCCOY.

The Elements of Physical Chemistry. By J. LIVINGSTON R. MORGAN, PH.D., Professor of Physical Chemistry in Columbia University. Fifth edition. New York: John Wiley and Sons. Small octavo, pp. xiv + 506. Cloth, \$3.00 net.

This book now appears in a fifth edition, and its general arrangement and Ostwaldian heredity are doubtless already familiar to those interested. The author remarks that, in this edition, the discussions of the phase rule and of the subject of colloidal solutions have been restricted, because special works on these subjects are now available. The system of notation employed has been changed throughout in order to conform to that adopted by the International Commission for the Unification of Physico-Chemical Symbols. The 238 problems comprised under Chapter X will still be found useful, in spite of the works of Prideaux and of Knox. The commendable effort to keep the book modern is perhaps more successful in individual detail than in general viewpoint. It is with regret that one finds that such errata have escaped notice as appear on p. 389: "The unit of electrical resistance is the *ohm*. . . . This is equal to 10^9 ergs. The unit of current strength. . . . is called the *ampere*—equal to 10^{-1} ergs. The unit of electromotive force is the *volt*, or 10^8 ergs." Truly, as Bret Harte would say, it were better for the student to know fewer facts clearly than more facts in a confused way. ALAN W. C. MENZIES.

Handbuch der Mineralchemie. DOELTER, *et al.* Vol. II, No. 6 (Bogen 1-10) and Vol. III, No. 5 (Bogen 41-50). Theodor Steinkopff: Dresden and Leipzig. Price, M. 6.50 each.

The editors of this work are to be congratulated that the European war has not lessened their output up to the present time, though the name of one of them, Dittrich, who has heretofore contributed the analytical methods, is conspicuously absent from this latest issue.

The contents of Vol. III, No. 5, is devoted chiefly to the mineral arsenates. They are mostly rare and have been the subject of little chemical work. There are only about a dozen references to work done in the last decade and a comparison of what there is about them with the matter

of a first-class mineralogy (Dana's) shows only slight additions. The subject of antimony is begun in this heft.

Vol. II, No. 6, deals with the important aluminum silicates. The anhydrous natural silicates are satisfactorily treated and the matter on porcelain is definite and adequate. The clay minerals, especially kaolin, possess great interest to the geologist and have been the subject of literally hundreds of investigations. Much of this work appears to be mere rubbish and its treatment in *Mineralchemie* seems to the abstractor open to serious criticism; page after page of futile experimentation is recorded in detail where a paragraph or two with references would have been all the matter is worth. This situation has occurred rather frequently in *Mineralchemie*, and while the effort of the editors to deal with all data in an unprejudiced manner is to be commended, definiteness and unity have often been inexcusably sacrificed.

E. T. ALLEN.

A Laboratory Manual of Qualitative Analysis for Students of Medicine, Dentistry and Pharmacy. By A. R. BLISS, JR., Professor of Chemistry and Pharmacy in the Birmingham Medical College. W. B. Saunders Company: Philadelphia, 1914. Octavo of 244 pages with 8 tables. Cloth, \$2.00 net.

This small book is even smaller than it appears, about one-third of the pages being blank to receive the notes of the student. Nevertheless the ground covered seems to the writer to be adequate to the needs of students of Dentistry and Pharmacy and of prospective students of Medicine. For medical students the book should be used during one of the preliminary college years, for there is certainly no time for this work in the better medical schools. In order to meet the increasing demands for preliminary training in chemistry before entering the medical school, Qualitative Analysis should, in the writer's opinion, encroach upon the laboratory time of the first course in college chemistry and be given in the second half of the freshman year. Only in this way can sufficient training in Organic Chemistry and Quantitative Analysis be obtained in the two years of college work now required for entrance to most of the good medical schools. In such a scheme this manual would be very serviceable, for it contains under each element, in addition to the usual qualitative reactions and plan of separation, a list of common compounds and especially of the "official" pharmacopoeial preparations.

An extensive knowledge of many of the latter preparations is perhaps of doubtful value to the physician, who has so many more important and more useful chemical facts and principles to learn, but the names and composition of the "official" compounds should at least be brought to the student's attention, and the inclusion of the list for consideration during the work in Qualitative Analysis seems to the reviewer desirable.

For students of pharmacy and dentistry and for students in those medical schools which still find it necessary to give Qualitative Analysis

as a part of the medical course, this book should also prove acceptable.

P. A. SHAFFER.

Traité Complet d'Analyse Chimique appliquée aux essais industriels par J. Post et B. Neumann, avec la collaboration de nombreux chimistes et spécialistes. Deuxième édition française entièrement refondue, traduite d'après la troisième édition allemande et augmentée de nombreuses additions par G. Chenu et M. Pellet. Tome troisième, second fascicule. Paris: Librairie Scientifique, A. Hermann et Fils. 1913. 465-902 pp. Price, 15 francs.

In this fascicle, itself a book of 438 pages, two related subjects are discussed: Coal Tar, and Coloring Materials. The general treatment is the same as in other fascicles, already reviewed in *THIS JOURNAL*,¹ and the same standard of excellence is maintained. Here again, however, as in the first instalment of this volume, the space does not seem to be equitably divided between the topics. It cannot be reasonably objected that 403 pages is too much to devote to pigments and to coal-tar dyes and their raw materials, vegetable dyes, dyeing and chemical tests. Coal tar is disposed of in 35 pages, but perhaps the excuse for this lies in the fact that both sections were written by G. Schultz, of Munich, so that any deficiency in one place can be remedied in another. C. E. W.

Der Nachweis organischer Verbindungen. Ausgewählte Reaktionen und Verfahren. VON L. ROSENTHALER, Professor an der Universität Bern. Die chemische Analyse. Sammlung von Einzeldarstellungen auf dem Gebiete der chemischen Analyse. Band XIX/XX. Stuttgart: Ferdinand Enke, 1914. Large 8, 1070 pp. Price, 34 Marks, unbound; 32.30 Marks, cloth.

The author explains in the preface that his aim has been to assemble upon a sufficient theoretical foundation the material facts of organic qualitative analysis which seemed to be of the most importance to the practicing analyst, after having verified and supplemented them, so far as possible, by his own observations. The result is probably the most comprehensive collection of analytical characterizations of organic compounds of all classes that has been brought within the compass of a single volume.

No rigid general scheme of procedure is laid down; but after a few sensible words of advice on the principles which will usually guide the analyst in planning his examination of unknown compounds or mixtures, and a section on the qualitative determination of the elements in organic compounds, the main portion of the book is given up to a series of descriptions of the analytically important reactions and properties of approximately three thousand compounds. The value of these characterizations is enhanced by the occasional discussion of methods for particular separations and extractions, and abundant bibliographical references. At the beginning of each chapter the analytical reactions of greatest importance for the class of compounds contained in it, and particularly such as are useful for

¹ *THIS JOURNAL*, 31, 120 (1909); 34, 752 (1912).

establishing the membership of individuals in the special groups, are clearly presented, and their uses indicated.

The grouping of the subject matter may be best indicated by naming the chapter titles. These are: Hydrocarbons; Alcohols; Aldehydes; Ketones; Carbohydrates; Phenols; Acids; Oxyacids; Ethers; Quinones; Esters; Halogen-derivatives; Nitro-derivatives; Nitroso-derivatives; Nitriles; Acid-amides; Amines; Acid-derivatives of Bases; Heterocyclic Bases; Amino-acids; Sulfur Compounds; Arsenic Compounds; Alkaloids; Resin Acids; Tannins; Glucosides; Bitter Compounds; Dyestuffs; Proteins; Enzymes; Toxalbumins.

A table of the compounds described, placed at the end of the book and arranged according to the elements present and the melting and boiling points, tends to lessen the difficulties arising from the lack of closer analytical coördination between the class reactions.

The author has done his work with care and discrimination, and the resulting volume, which is attractive in appearance, will prove a valuable book of reference.

S. P. MULLIKEN.

Applied and Economic Botany. By HENRY KRAEMER. Especially adapted for the use of students in technical schools, agricultural, pharmaceutical and medical colleges, and also as a book of reference for chemists, food analysts and students engaged in the morphological and physiological study of plants. 8°. Pp. vi + 806, with 424 plates comprising about 2,000 figures. Philadelphia, published by the author (145 N. Tenth St.), 1914. Price, \$5.00.

Two addresses, respectively by the President of the Botanical Society of America and the Chairman of the botanical section of the American Association for the Advancement of Science, at the recent Convocation Week meetings in Philadelphia, present the very different viewpoints from which botany, like the other sciences, must be seen by those to whom the privileges and duties of teaching fall. The practical utilization of every one of the fundamental sciences has become so great that the teacher can hardly make peace with his conscience if he lets his one opportunity, with students who take an introductory course only, go by with little or no reference to its applications, while those to whom the arts based upon it and other sciences are of more direct interest than the science itself are impatient of the use of their time and effort for more of the latter than they see or believe to be of practical use. This is true of the sciences directly fundamental to engineering, agriculture, and the like, for instance, to such an extent that in the former, to which physics is indispensable, its teaching has become so specialized that in a great university with a strong college of engineering, the general student who has escaped physics in the secondary school may have difficulty in finding opportunity in college to learn the salient facts and relations in physics that every intelligent person needs; while a civil engineer who is to know the distinguishing

marks of structural timber, or the sanitary engineer who is to recognize the danger line in the bacterial contents of drinking water, must acquire the desired knowledge with little or no understanding of the structure and life of plants which forms the essence of an intelligent comprehension of our every-day dependence upon these humble relatives of mankind.

Professor Kraemer is a seasoned teacher in the field of pharmacognosy, in which, almost to our day, a general knowledge of botany has been considered indispensable, and which, even now, he and those of his training and practice are unwilling to reduce to an art divorced from the underlying science. The present book is doubly interesting as a concrete exposition of this viewpoint and a compendium of reference for the botanical facts most frequently desired by pharmacists and organic chemists, to whom the source and origin of their materials are important. It is the outgrowth of long experience in the laboratory, and may be regarded as the most mature expression of the author's views, since it replaces earlier books from his pen in the same field. Dealing primarily with the structure and products of plants, it is necessarily lacking in the full analysis of their activities that the agriculturist is coming more and more to recognize as fundamental to agronomy—though physiology is by no means excluded from its pages; but a student who had really mastered its contents in the laboratory would form excellent material for the development of a specialist in any field of botany, if he had absorbed at the same time the spirit of investigation that its intelligent use ought to foster.

Little need be said in detail of the contents of the book, further than that it is modern and accurate as these attributes may be applied to a compendious work of its kind. An outline of the vegetable kingdom occupies about one-fifth of its space, with a chapter on organic evolution. Somewhat more concerns the contents and forms of cells, and a like part is given to the external and internal structure of plants. Chapters on botanical nomenclature and terminology and on the cultivation of medicinal plants give a reference character as valuable as it is unusual in books usually accessible to those who are neither botanists nor pharmacists; a far too short chapter presents the essentials of technique as practiced by the student of drugs; and over one-third of its bulk consists in a synopsis, at once readable and instructive, of the vegetable kingdom and its products. Not the least of its merits is that the book is fully indexed.

WILLIAM TRELEASE.

Chemistry of Common Things. By RAYMOND P. BROWNLEE, ROBERT W. FULLER, WILLIAM J. HANCOCK AND JESSE E. WHITSIT. Allyn and Bacon: Boston, New York and Chicago. 1914. viii + 616 pages. Price, \$1.50.

The authors of this book are teachers in high schools of New York City, and their work is an attempt to satisfy a practical requirement in public school teaching by furnishing a manual which "is designed to meet the

growing demand that high school courses should 'prepare the pupil for citizenship;' it therefore deals with the chemistry of everyday affairs.

The authors have shown great industry in bringing together a large number of facts relating to applied chemistry. The compilation might almost be described as an elementary chemical technology and if a student is interested at all in the things which go on around him he should find much in this book that is entertaining and probably helpful.

There is no attempt at a presentation of the principles of chemistry in a systematic way and not much is given in the nature of general chemical theory. The course is not intended for "discipline," but to impart information to that large class of young people who never expect to go to college. Such information must be of necessity somewhat superficial, but, all things considered, it is perhaps the wisest plan. Teachers are divided on this point. The reviewer believes that the greatest mistakes are made in trying to follow a rigorously scientific method with beginning students; it sometimes happens that at the end of the freshman year the boy has neither facts nor discipline, and after a high school course the situation may be, if possible, even worse.

The present book contains, however, too much material for high school purposes and the authors admit that only portions of it can be used. It shows frequent evidences of hasty preparation, calling for not a few corrections in future editions. For example, the equations on pages 9 and 10 illustrating the action of iodine on mercury and of oxygen on phosphorus should be changed. In one of the early chapters boric acid is described among the important acids. The erroneous statement is made that it and its salts are largely employed as food preservatives. In the attempt to give some information on an unusually wide range of topics this information is frequently incorrect as well as superficial. An example of this is shown in the discussion of alcoholic beverages on pages 218 and 219. The water analysis quoted on page 169 would doubtless prove somewhat confusing to a beginner. But these and other faults may be easily corrected in future editions.

J. H. LONG.

Lehrbuch der physikalischen Chemie. By JELLINEK. Ferdinand Enke, Stuttgart, 1914. Vol. I, 732 pp. Unbound, 24 marks; bound, 34 marks.

This is the first volume of a treatise on physical chemistry, which the author intends to carry out in the characteristic Teutonic spirit of exhaustive research. We may hope that the present war will not prevent its ultimate accomplishment.

The completeness of the author's scope is indicated by the fact that the 732 pages in the present volume suffice merely for the consideration of the fundamental laws of chemistry and thermodynamics and for the consideration of matter in the gaseous and liquid states.

The author's treatment is largely conventional, as it should be in a work which is to serve as a compendium of existing knowledge. The general method of treating any particular field of investigation is to discuss in turn the experimental methods, the experimental results and their theoretical interpretation. Without being offensively elementary the presentation is pedagogical in the best sense, thus permitting the use of the book by chemists not previously familiar with the particular field treated. The complete references to the literature will prove of special value.

The author's presentation of the principles of thermodynamics seems very clear and satisfactory. He defines free energy in the familiar Helmholtz form which makes the decrease in free energy equal to the maximum obtainable external work instead of the maximum work minus the imposed work, which is the definition more often used in chemical calculations. Let us hope that he will stick to his own definition more consistently than is the custom of German chemists.

The author has very wisely postponed the presentation of the Nernst heat theorem until a later portion of his work. In spite of the fact that valuable principles are certainly connected with the Nernst theorem and that considerable progress in the way of systematic presentation has been made by Planck in the third edition of his *Thermodynamics*, it seems to the reviewer that the exact definition and significance of the principle is still a problem for the future. The reviewer hardly believes that it will be possible, as Jellinek apparently intends, in his later treatment, to identify the Nernst heat theorem with the principle stating the impossibility of attaining the absolute zero of temperature, since this principle is one which has long been familiar to thermodynamic thought.

The specific heat of gases is treated from the standpoint of the simple Einstein quantum theory, which to the reviewer certainly seems less unsatisfactory than any of the more complicated quantum theories, all of which are in a rather unsatisfactory stage of development.

The book, if brought to completion, will certainly rank as a standard treatise on physical chemistry, and will perform a valuable service for which Ostwald's *Allgemeine Chemie* becomes less adequate as the science of physical chemistry advances. Even with only one volume published it is a valuable contribution to systematic knowledge and might well find a place in every library of physical chemical books.

RICHARD C. TOLMAN.

Die Wasserstoffionenkonzentration. By PROFESSOR DR. LEONOR MICHAELIS, Privatdozent an der Universität Berlin. Julius Springer, Berlin, 1914. xiii + 210 pp. Price, M. 8.

This book is the first volume of a series of "Monographien aus dem Gesamtgebiet der Physiologie der Pflanzen und der Tiere," and its purpose

is primarily to show the absolute necessity of considering the hydrogen ion concentration in biological processes, and to explain clearly how it can be measured.

The author considers, first, the theoretical meaning of the "hydrogen number," *i. e.*, the logarithm, with the minus sign omitted, of the hydrogen ion concentration. This division includes discussions of the dissociation of water, acids, bases and amphoteric electrolytes, the hydrolysis of salts, the influence of the hydrogen ion concentration on the coagulation of colloids, and its influence upon the action of the most important ferments.

The second division gives experimental results on the hydrogen ion concentration in various fluids of the living organism.

The third main division of the book describes the theory and technique of the measurement of the "hydrogen number" by means of the hydrogen electrode and by means of indicators. There is included also a discussion of the preparation of solutions of definite hydrogen number.

There has been a great need for just such a book as this, and the author has succeeded in filling it admirably. In books which seek to place the methods or results of one branch of science at the disposal of another, one often finds a superficial knowledge of one field or the other, but the author of the present work writes neither as a physical chemist assuming the role of prophet to the biologists, nor yet like a biologist who has acquired a smattering of physical chemistry. The book should, therefore, prove of great value not only to biologists but also to many of the chemists who need the information that it gives.

THE COMPLICATIONS AT THE ANODE IN THE SILVER COUL-
OMETER (VOLTAMETER).

BY T. W. RICHARDS AND F. O. ANDEREGG.

Received February 13, 1915.

In a recent paper we have emphasized anew one of the important causes of error in the silver coulometer, namely, inclusion of mother liquor in the precipitate.¹ A definite decision concerning this matter necessarily preceded the discussion of all other questions involving the weight of the cathode deposit, on account of the fact that included matter may seriously affect this weight. A brief repetition of the main conditions is perhaps in order.

(1) It was shown that the amounts of inclusion are highly variable, being dependent upon extent of surface covered by the cathode deposit and the roughness of surface of the cathode, as well as upon the presence of some kinds of impurities. The rate of deposit is doubtless also of moment; and yet other circumstances may affect the outcome.

(2) When the solution is very pure, the extent of surface limited and the surface smooth, the amount of inclusion may be very small (as little as 0.004%), but it is not safe to rely upon its constancy, unless very unusual precautions are observed. With reasonable but not excessive precautions

¹ Richards and Anderegg, *THIS JOURNAL*, 37, 7 (1915).

the amount may be seven or eight times as great, even when using materials much purer than these ordinarily obtainable.

(3) Although the amounts of inclusion may thus be quite different under different conditions, sufficiently accurate results may be obtained if the volatile portion of the enclosed mother liquor is expelled by heating the deposit to dull redness. Therefore, this should always be done, applying the correction mentioned in paragraph (5) below.

(4) Part of the included mother liquor is enclosed between the crystals and the dish, and part entirely within the silver crystals.¹ The proportions thus distributed doubtless vary with the conditions. Of the former part, a portion may be evaporated at 160°, but probably not all of it.² For this reason satisfactory quantitative results concerning the amount of the inclusion may not be obtained from the crystals after scraping them from the dish; for some water is probably evaporated, and some silver nitrate is certainly left on the dish, when the intervening cells are opened by the abrasion.

(5) In the most accurate work correction should be made for the residual silver left by the decomposition of the enclosed mother liquor. As the amount thus left is very small, it is not necessary to know the exact concentration of the liquid; an approximation will suffice.³

(6) *The really essential point is to determine the true weight of pure silver deposited by the current from a sufficiently pure solution.*

(7) All these conclusions essentially confirm and amplify the Harvard

¹ Hulett and Vinal have found in some recent interesting experiments (*Bull. Bur. Stand.*, 11, 553 (1914)) that silver in contact with platinum is perceptibly soluble in water. That this solubility was too small to affect the question under consideration is shown by the fact that our crucibles with the adhering silver, after thorough washing, could be allowed to stand for many hours filled with pure water without imparting enough silver to that water to show in the nephelometer. Accordingly, the silver nitrate which we found upon the scraped crystals and upon the battered electroc from which they had been removed, must have been really the result of included mother liquor. Upon our other comparative results the solubility of silver in water would have no effect as all samples were treated in practically the same way.

² The cells are evidently, some of them, opened by the high steam pressure at 160°, the crystals having been loosened by the difference between the coefficients of expansion of silver and platinum. Water imprisoned wholly within the silver walls of cells in detached crystals requires, as has been repeatedly stated, a dull red heat for its liberation.

³ It is clear that the evaporation of part of the included mother liquor complicates estimation of the amount of silver nitrate included, but, fortunately, the possible error is very small. The resulting surplus of silver nitrate is partly balanced by the fact that the enclosed catholyte must have been somewhat depleted. Therefore, for ordinary cases it is safe to conclude that the residual silver must weigh about 6% or 8% of the total inclusion from a 10% solution. Of course, for work of the very highest accuracy (beyond 1 part in 100,000) the exact nature of the inclusions must be determined and a more complete method must be used.

results of 1902.¹ We believe that they are also in essential accord with the heretofore published results of Hulett, making allowance for certain differences of detail already mentioned.

Before our further experiments are recounted, a few words about the history of the question may not be out of place, although a detailed discussion of the very voluminous literature would occupy too much space for the present publication.

In the early work at Harvard it had been shown that the older form of voltameter, containing filter paper as originally designed, invariably caused a deposit distinctly heavier than that in which the anode liquid is kept away from the cathode.² At least part of this effect was referred to a temporary surcharge of silver in the anolyte. The need of a substantial inorganic septum to separate this liquid being indicated, a porous cup was employed, and the use of filter paper entirely abandoned. More recently Rosa and his collaborators have concluded, on the basis of extended experiments, that part of the effect is due to a specific action of filter paper and not to the surcharge of silver.³

There has been much discussion of these conclusions, but unanimity of opinion does not seem to have been attained.⁴ A study of the published experiments seems to indicate that both of the effects are probably operative at the same time; nevertheless, on account of the divergence of opinion, it seemed worth while to make further experiments concerning the nature of the anode liquid under varying circumstances. The present paper recounts the fulfilment of a portion of this program.

In studying this problem two different methods were used in the investigation to be described. In the first place, the weights of the cathode deposits in different forms of coulometers arranged in series were compared. These coulometers were so planned that the access of the anode liquid to the cathode was greatly varied, in some cases almost all of it being

¹ Richards and Heimrod, *Proc. Am. Acad.*, **37**, 415. On page 436 occur the following words: "It is evident that the amount of included mother liquor required varies according to the rate and mode of deposition;.....but in applying a correction one should obviously use the value found in the particular investigation under review."

excluded, and in other cases much of it being admitted to the cathode. The various results thus obtained show that the anode liquid really contains an excess of silver, which it deposits with the normal crystalline precipitate, provided that the transfer is rapidly made.

Again, other experiments were instituted in which it was shown that silver plates immersed in fresh anode liquid, but not electrically connected, definitely gain in weight in that liquid. This outcome substantiates the other.

Comparison of Different Forms of Coulometers.

The modifications of coulometer which were compared in the experiments to be described were as follows: First, two standard coulometers, each precisely similar to that used by one of us with the assistance of G. W. Heimrod twelve years ago, were mounted. They consisted of large lipped crucibles, each weighing about 60 g. and containing about 120 cc., within which were suspended from glass arms small, porous, cylindrical Pukal cups which contained the anolyte, always at least 1 cm. in level below the catholyte.¹ One of these crucibles was employed in moderately roughened condition, caused by long using, and another was highly burished. To test the effect of size, a much larger but otherwise similar porous cup coulometer, containing over 300 cc. and having twice the surface, was used; and to test the effect of the anode liquid a very permeable cup was substituted for the fine-grained one.

These instruments were not only compared with one another, but also with the older forms. In two tests the porous cup was omitted and filter paper substituted, and in many other tests we used various modifications of the Kohlrausch form (in which neither a porous cup or filter paper are employed, but a small, glass dish is placed beneath the anode), because much use has recently been made by others of this form. The object of the glass dish, as avowed by the designers, was merely to catch the so-called "anode slime" or finely powdered deposit of silver which falls from the anode during the progress of electrolysis, since they did not fear any harmful effect from the anode liquid. In preliminary experiments we tested the original form of Kohlrausch coulometer carefully and found it unsatisfactory, partly because the "anode slime" frequently floats upon the surface of the electrolyte and becomes mixed with detached crystals from the cathode. Moreover, the cathode deposit is formed only near the top of the dish, most of the surface of the platinum cathode being useless because protected by the glass cup. This unmodified form was therefore rejected.

The original Kohlrausch coulometer has been modified in various ways. The form used at the Bureau of Standards had a glass ring at the surface around the anode to prevent the dissemination of the anode slime (a

¹ For further particulars, see *THIS JOURNAL*, 37, 11 (1915).

phenomenon noticed by others as well as by ourselves). Moreover, the form devised by Smith has the anode placed well down in a glass cup, and has the glass ring extended into a cylinder, which at the end of the experiment may be lowered upon the cup, thus enabling the experimenter to remove the "anode slime" and anode liquid together. This, although not different in principle, is doubtless the most easily handled modification of the Kohlrausch instrument, and is perhaps as near an approach to the porous cup as one can obtain from glass apparatus; but it is neither as convenient nor as efficient for removing the anode slime as the porous cup, and, moreover, is certainly less suitable for preventing the diffusion of the anode liquid.

In our experiments, besides the porous cup instruments, two forms of Kohlrausch coul-

ometer were finally used; first, one in which the anode was chiefly above a glass cup suspended in the electrolyte; and, secondly, one in which

B, Glass ring for supporting porous cup.

C, Silver anode.

D, Porous cup.

E, Platinum cathode (a large lipped crucible).

the anode was sunk entirely below the edges of a similar but deeper glass cup similarly suspended, the conducting wire to the anode being protected by a glass tube. In both forms the "anode slime" which accumulated at the surface was prevented from spreading by glass rings. The second of these two forms was essentially similar to that used by the Bureau of Standards under the name of Poggendorff coulometer, and is similar in principle to the Smith form, except that because our cup was deeper than theirs, it was probably a more efficient apparatus. In both these forms of Kohlrausch coulometer, the silver was deposited only on the upper half of the crucible which formed the cathode as before.

The first step in any such work is the careful testing of the standard of reference. This had indeed been carried out carefully by one of us with the help of G. W. Heimrod years ago; moreover, the consistency of results thus obtained with the help of the porous cup coulometer has been supported by various other experimenters, especially the Bureau of Standards, if we assume that the amounts of inclusion were fairly constant in experiments under similar conditions. The higher results obtained with large coulometers have already been shown in our previous paper to be doubtless due to greater inclusion of mother liquor in these cases, and, therefore, these results do not in the least militate against the results obtained with the porous cup instrument. Because of the great bulk of earlier work, but few new trials were necessary here; and these are recorded mainly in order to show that all was in order for the exact prosecution of the present research.

The following table shows results with the porous cup coulometer in which, first, a somewhat roughened cathode was compared with one very highly burnished, and, secondly, results in which the same coulometer was compared with the larger instrument, with about twice the surface and nearly three times the volume, but otherwise the same. The weights given below are those of the precipitates after ignition at incipient redness,¹ corrected for the small amount of silver (never exceeding 0.03 mg.) left by the mother liquor, which was driven off by the heat. This quantity, it may be remembered from our previous paper, was assumed to be 6% of the included mother liquor. The amount of included mother liquor was least in the small, smooth vessel; next in the small roughened vessel, and greatest in the large coulometers. The actual amounts of inclusion are given among the results tabulated in our last paper² and do not con-

¹ This measure of temperature, rather than a more exact and elaborate one, was used because it is easily available to everyone. Carefully measured, the temperature used by us was found to be between 590° and 630°. Experiments are now in progress here testing the effects of various carefully measured temperatures on the weight of precipitate.

² THIS JOURNAL, 37, 16, 20 (1915).

cern us here, for here we are concerned only with the true weight of silver deposited.

TABLE I.—COMPARISON OF POROUS CUP COULOMETERS UNDER VARYING CONDITIONS.

4.....	3.13805	3.13807	+0.02	+0.0006

Average error, —0.0004

Evidently, the so-called "volume-effect," which has so much troubled several investigators, has been entirely vanquished. Even considerable variations in the size and condition of the cathode make no important difference in the weight of silver obtained after ignition, all of these values being within the limit of error of experimentation. Such slight variations as exist are all in the direction indicating that the residual silver from the decomposed inclusions was slightly more than 6%—a condition which must occur if some of the cells had been opened and dried at 160°, but the error never reaches 0.001%; and as the weighings could hardly be relied upon to more nearly than 0.02 of a milligram, it is safe to conclude (as one of us concluded fifteen years ago) that the porous cup coulometer is capable after ignition of giving very constant results, and, therefore, is well suited for a definite standard of comparison.

The next step in the experimental work was obviously to repeat the comparisons, so often made by others, of the weights of silver precipitated in the other forms of coulometer with those obtained from our standard instrument, bearing in mind, nevertheless, the fact that the precipitates contained varying contamination with included mother liquor, and allowing in each case for the individual amount.

With each form of Kohlrausch coulometer a series of comparisons was made with the typical standard porous cup coulometer. In order to make the results as clear as possible and to relate them directly to the recent results of others, there is given in the first table below a comparison of the weights of the precipitates not ignited, but merely carefully washed and dried at 160°, after the manner of the several National Bureaus.

The outcome is striking. Each form of Kohlrausch coulometer is seen to give almost exactly the same results as the porous cup coulometer, just as other experimenters have found. The average result shows that in nearly 16 g. of precipitate the surplus shown by the Kohlrausch coulometer was only 0.14 mg., an error of less than one part in 100,000. It is from data of this sort that so many able experimenters have concluded

that there is no such thing as an anode impurity, that the porous cup is unnecessary, and that no inclusions are present in the cathode deposit.

		15.76796	15.76810	+0.14 Av.,	+0.001

Our preceding article has demonstrated, however, that the weights given in this table do not represent pure silver, but rather silver in which there is enclosed varying amounts of mother liquor in microscopic cells; hence this apparently satisfactory comparison has really little significance. The real comparison, which alone can show whether there is appreciable impurity evolved at the anode, capable of augmenting the weight of the deposit, is only to be found when the *true* weights of the silver deposited are determined by igniting the precipitates in each case, with due precautions. This had, of course, been subsequently done in each case recorded above; and Table III below presents the weights of pure silver thus found. Each of these weights is corrected for the 6 per cent. of silver assumed to be left behind by the expelled electrolyte.

TABLE III.—COMPARISON OF TRUE WEIGHTS OF PURE SILVER DEPOSITED IN TWO FORMS OF COULOMETER.

	No. of expt.	Porous cup voltameter. G.	Kohlrausch coulometer. G.	Surplus in Kohlrausch forms.	
				Mg.	%.
First series	1	2.84998	2.85017	+0.19	} Av. = 0.006
	2	3.07714	3.07727	+0.13	
	3	2.29095	2.29111	+0.16	
Second series	4	2.18540	2.18554	+0.14	} Av. = 0.003
	5	3.05539	3.05548	+0.09	
	6	2.30721	2.30727	+0.06	
		15.76607	15.77684	+0.77	

Evidently in every single case the Kohlrausch coulometer gave a distinctly greater deposit of *pure* silver than the porous cup coulometer. Moreover, it is very striking that in the first series (Experiments 1, 2 and 3), where the anode was above the glass cup (giving more chance for diffusion), the surplus was much more marked than in the second series

(Experiments 4, 5 and 6), where the anode was sunk well within the glass cup. The surplus is so consistent and so much beyond the limit of error that there can be no question of its real existence.

The close agreement of the figures shown in Table II is, therefore, shown to be illusory. The reason why the porous cup and Kohlrausch voltameter appeared to give the same results was simply because in the Kohlrausch form the error of a surplus of silver from the anode was hidden by the fact that in this form the inclusions were less than in the porous cup form. The reason for the smaller amount of inclusion in the Kohlrausch form has already been shown to be due primarily to the smaller surface upon which the silver was deposited, although it may perhaps be referred partly to the different form of aggregation in larger crystals, which seems to occur when small amounts of anode liquid escape into the catholyte.¹

As has just been pointed out, the inclusions in the Kohlrausch form are less than those in the porous cup form. Evidently the amount of inclusion on the one hand and the surplus from the anode on the other hand are independent variables, and neither can be certainly predicted from a knowledge of the other.

Having thus explained the illusory agreement observed at first, and having demonstrated that a real (if slight) surplus of silver is deposited even by the best type of Kohlrausch coulometer, we may proceed to show that under conditions where the anode liquid is allowed more freely to reach the cathode, a considerably larger surplus of silver may be obtained. This indeed had been demonstrated in the early Harvard work of 1902, but much of the evidence in that work depended on a comparison of the deposit in the coulometer containing filter paper with the porous cup form, and hence some doubt might legitimately exist, as others have pointed out, whether the surplus had not been caused by the filter paper.² We shall return later to this point. It is easy, however, to promote the diffusion of the anode liquid to the cathode without introducing filter paper. All that it is necessary is to keep the liquid within the porous cup at a higher level than the liquid outside (instead of at a lower level in the manner always from the first maintained in the standard coulometer). This was done in some of the early Harvard experiments, and the result was published, although the experiments were not reported in detail and have been usually overlooked.³ Buckner and Hulett also afterwards repeated a comparison of this kind and showed that, as a matter of fact, in such cases the surplus of silver is obtained upon the cathode, using a porcelain

¹ THIS JOURNAL, 37, 16 (1915).

porous cup.¹ Nevertheless, it seemed worth while to repeat these experiments once more.

In the trials recorded in Table IV below, the standard porous cup coulometer was placed in series with a coulometer containing a more permeable "alundum" cup, in which the liquid was kept at a higher level inside than out, promoting diffusion as mentioned above. The "alundum" cups (which had been chosen for the purpose because they were much more permeable than the Pukal cups) were carefully tested in order to be sure that they could have no reducing action on the silver nitrate. Professor Hulett has since informed us that in some cases he had detected such action, but none was found in our samples, so that the following results are significant: The "alundum" cups (like the porcelain porous cups in all our other experiments) were not only thoroughly washed with nitric acid and water, but were also soaked in silver nitrate (as recommended by the Bureau of Standards) before being used.

* Among the five trials recorded in the table, two of the electrolyses in series were conducted in the usual way, the precipitates being ignited at incipient redness as usual. The other three were conducted under the same conditions, but the weight of ignited silver was calculated from that of the silver dried at 160°, it having been obtained under the usual conditions maintained in the first two experiments. These calculated values are enclosed in brackets in the table; although not quite as certain as the more directly obtained results, they are sufficiently accurate for the purpose in hand.

The surplus of silver evident in Table III has been markedly increased in Table IV, the average in the latter series being more than double that found in the Kohlrausch coulometer where the anode was raised above the glass cup, and nearly five times that found in the form wherein the electrode was sunk within the glass cup. Probably even the "alundum" cup is not the best apparatus for demonstrating the effect of this anode liquid, for after the electrolysis is well started, the cup is partly filled with "anode slime," and the anode liquid must penetrate through this in order to escape. Because (as will be shown) the anode liquid deposits silver upon a silver surface, it must lose some of its surcharge by depositing this upon the finely divided metal of the "slime." A yet quicker removal

¹ Buckner and Hulett, *Trans. Am. Electrochem. Soc.*, 22, 379 (1912).

of the anode liquid from the neighborhood of the anode and its powdery environment would probably give a yet larger discrepancy as compared with the standard porous cup coulometer. In this connection it seems worth while to record two new experiments in which loosely wrapped filter paper took the place of the porous cup.

TABLE V.—COMPARISON OF STANDARD POROUS CUP COULOMETER WITH FILTER PAPER VOLTAMETER.

There can be no question that a real excess of silver was deposited on the cathode.

Clearly, precipitates obtained in the coulometer when the anode is guarded only by filter paper are too heavy before ignition for two reasons: in the first place, mother liquor is included; in the second place, an excess of silver is precipitated. The further discussion of the action of filter paper will, however, be postponed to a subsequent paper.

Spontaneous Deposition of Silver from the Anode Liquid after Electrolysis.

In the experiments, published in 1902, made with the help of G. W. Heimrod, it was shown that the anode liquid was capable, not only of depositing an excess of silver on the cathode during electrolysis, but also of depositing silver upon a separate silver plate without any electrolytic help. In other words, it was shown that the anode liquid thus obtained had a surplus of reducible silver, which would at once crystallize on a silver surface, if it was allowed to do so before the oxygen of the air had a chance to oxidize it. Although other evidences of such behavior of the anode liquid were furnished, these results have been interpreted by others as due to the action of filter paper, and it is true that if such action existed it might account for a part of the effect, for filter paper was present. Therefore, it seemed desirable to repeat the experiment in such a way as to exclude organic matter. The problem was easily accomplished in the following fashion: The anode in a voltameter such as that used in the preceding experiments, was surrounded by a cup of easily permeable "alundum" and this in turn was surrounded by a somewhat larger, very fine-grained Pukal cup, in which the level of the electrolyte was kept below that in the inner "alundum" cell. The Pukal cup was immersed in the usual fashion in the electrolyte in the large platinum crucible-cathode, and the electrolysis was conducted as usual. During the progress

of the electrolysis, however, portions of the liquid permeating from the inner "alundum" porous cup were quickly removed by means of a fine pipet from the narrow space between the two cups, and were immediately transferred to a small porcelain crucible containing a small plate of carefully weighed silver. This plate in nine successive trials was found to gain a total of 0.62 mg., an average of 0.07 mg. in each trial. The silver plate became covered, during these trials, with a curious iridescent covering, which, when examined by a powerful microscope, was seen to consist of very fine, brilliant, crystalline laminae, probably due to the deposition of silver. But whether this was silver or something else, the essential point remains, namely, that the plate had accumulated a deposit which augmented its weight.

In order to be sure that this deposition could not be due to some impurity from the "alundum" cup, four trials were made in which precisely the same procedure was conducted, taking solutions from between the two cups, except that no current of electricity was allowed to pass. The silver showed the following gains in these successive trials: +0.01, +0.01, -0.02, +0.00 mg., total change in weight, 0.00 mg.

This indicates, not only that the weighing and method were sufficiently accurate, but also that the deposit found when the current was running could not have been due to any action of the alundum cup, but must have been due to a real addition of something (probably silver) to the liquid between the cups, and this could have come only from the anode. The result, which evidently confirms the conclusion of years ago, affords convincing direct evidence of the cause of behavior of the anode liquid observed in our other experiments. As some of the anodes in the trials just described were of fused silver, whereas others were of silver deposited electrolytically, and precisely the same average gain was noted with each class of anode, it is clear that the special form of the silver at the anode is unimportant. The production of this easily reducible surplus of silver is thus a general phenomenon.

The reason why others have failed to find this effect and, therefore, have doubted its existence, is unquestionably because they have allowed too much time or too great dilution of the anode liquid to intervene before the liquid was brought into contact with a silver surface. This would give an opportunity for oxidation, which would remove the peculiar compound causing the effect, producing a slightly basic solution capable of depositing nothing upon a silver surface, at least without electrolytic help. That a negative result is thus obtained, we have found by various experiments, which need not, however, be given in detail.

It seemed a matter of interest to discover also if filter paper alone could affect the weight of a silver plate wrapped in it and immersed in silver nitrate solution, that is to say: to discover if filter paper can produce

a silver compound capable of depositing silver in crystalline form upon a silver surface without electrolytic help. Accordingly, a silver plate was wrapped in purest quantitative filter paper, placed in a pure solution similar to that used in the regular electrolyses, and subjected to the same conditions as to length of time of standing and temperature as before. Eight successive trials showed a total gain of 0.01 mg. in the weight of the silver plate—a wholly negligible quantity. This shows that filter paper does not promptly produce in silver nitrate a compound like that produced at the anode, which is capable of depositing silver spontaneously upon a silver plate, and it removes entirely whatever doubt there may have been concerning the experiments of 1902 upon this subject.

A hypothetical explanation of the nature of the anode liquid was approved in 1902.¹ Although at the time this hypothesis was accepted only tentatively without insistence upon its final verity, no facts have been brought forward by others which seem to diminish the cogency of the argument. Therefore, it seems to us still the best explanation for the behavior of the anode solution. In brief, the hypothesis supposes that a complex ion, such as Ag_2^+ or Ag_3^+ , containing silver in a state of lower average valency than usual, is set free at the moment of the attack on the anode; that is to say: some of the silver which is properly ionized by the current carries away with it some of the anode metal, which really ought to have been left behind. This complex, not being in equilibrium with the solution, immediately decomposes,—its rate of decomposition decreasing, of course, as its concentration decreases. Most of it must decompose in the immediate neighborhood of the anode, the presence of the silver there expediting the decomposition, just as the presence of crystals of a salt relieve its supersaturation. When, however, the anode solution which contains only a slight concentration of the complex silver ion is removed from a silver surface, it is to be supposed to be more permanent, and may remain in a metastable condition until either oxidized by the dissolved oxygen in the electrolyte or precipitated upon the silver at the cathode,—which also, of course, is able to relieve the supersaturation and reduce the metastable to a stable equilibrium. Although this explanation is avowedly hypothetical, it seems to us to cover the ground and to be entirely consistent with itself and with all the facts, explaining the existence of the anode slime as well as the peculiar behavior of the anode liquid in every detail. Whether or not a portion of the anode slime, so finely divided as to be almost colloidal, may be responsible for at least a part of the phenomena

¹ *Loc. cit.*, p. 432. Novak seems to have been the first to propose this explanation (*Proc. Roy. Bohem. Acad. Sci.*, 1, 387 (1892)) and Rodgers and Watson offered independently a similar one [*Phil. Trans.*, 186A, 631 (1895)]. Reference may also be made to the work of Bose [*Z. Electrochem.*, 13, 477 (1907); 14, 85, 314 (1908)]; Luther [*Z. physik. Chem.*, 30, 628 (1900)]; Jellinek [*Ibid.*, 71, 513 (1910)], and Eisenreich [*Ibid.*, 76, 643 (1911)].

recounted in this paper, we have no means at present of deciding, but this explanation seems, on the whole, less adequate than the one just discussed. We shall hope for more light upon this question in the near future. Whatever explanation may be finally accepted, the desirability of keeping the anolyte away from the cathode by means of an effective diaphragm seems to be strongly indicated by the experiments described above.

The Nature of the "Anode Slime."

In the early Harvard papers it was suggested, as already remarked, that the hypothesis of the complex ion was capable of explaining the nature of the "anode slime." This point does not seem to have claimed the attention of others, but, nevertheless, it is worth reiterating because it is in accord with our explanation of the behavior of the anode liquid.¹ The anode dust was then found to be composed of extremely fine crystals of silver, as seen in the microscope; and we are to confirm this observation. Although it is conceivable that these crystals were left behind when a portion of the silver dissolved, it seems more probable that they are the result of the decomposition of most of the complex ion, which deposits its extra load in the form of this fine crystalline powder. With a large anode, the equilibrium at any one spot would be less difficult to maintain, hence the amount of the "slime" would be less, as the Bureau of Standards have found. That the total loss at the anode should nearly correspond to the gain at the cathode, as several investigators have shown, is not in the least contradictory to this theory, for when all the anode slime is collected and weighed with the anode, it is clear that the only weight lost must be due to such portion of the complex ion as escaped from the anode and became oxidized. In the siphon form employed, this amount would probably be very small, as the heavy anode liquid remained at the anode.² Hence, the loss at the anode and the gain at the cathode might be equal, although each might be too great. The irregular results obtained at Harvard in 1902 substantiate this explanation.³

No other theory seems to explain the existence of the anode slime and its peculiar finely divided nature as well as this.

The Efficacy of the Porous Cup as a Means of Retaining the Anode Liquid and "Anode Slime."

The above results make it perfectly clear that, in order to obtain an accurate result in the coulometer, the anode liquid must not be allowed to reach the cathode. Any device which effects this separation and permits the ready weighing of the cathode deposit should be adequate for the purpose. It is shown above that the Kohlrausch plan, which was intended originally only to collect the anode slime, serves also in part to

¹ Richards and Heimrod, *Proc. Am. Acad.*, 37, 432 (1902); *Z. physik. Chem.*, 41, 319 (1902).

² Compare *Bull. Bur. Stand.*, 10, 528, 536 (1914).

³ *Ibid.*, pp. 434 and 321, respectively.

prevent the anode liquid from reaching the cathode. But this apparatus is unsatisfactory, because even when the anode is deeply sunk within the glass cup, some excess of deposit on the cathode seems to be obtained, and in any case the anode slime is troublesome, and not always content to remain within bounds. Therefore, these forms, although better than the filter paper voltameter, do not seem to be the best.

Another device suggested by Merrill¹ places the cathode at the top and the anode at the bottom. As tested in 1902 at Harvard, it was modified by using a wire gauze as the cathode, to facilitate the escape of the depleted catholyte.² This arrangement, if the time of electrolysis is not too long and the vessel is not disturbed, secures a satisfactory exclusion of the anode liquid from the cathode; but it is hampered by the disadvantage of the possibility of the loss of small crystals from the cathode, which may fall upon the anode, and become mixed with the anode slime. It is useful when the experimenter desires that the resistance of the coulometer should remain nearly constant throughout the electrolysis.

The syphon voltameter, in which the anode and the cathode are in different vessels, has the disadvantage of interposing large resistance, which evolves heat and rapidly changes, even in the most advantageous form used by the Bureau of Standards, where the syphon is very wide and short. The reason why this has been found occasionally to give too large deposits can hardly be traced until the inclusions in such deposits have been determined. The excess is probably not due to the anode liquid, which, except in the shortest syphons, probably stays entirely on the anode side.

The elimination of these forms of coulometer leaves the porous cup coulometer as the only remaining form worthy of consideration. Therefore, it behooves us to discuss very carefully its virtues and its faults.

In the first place, it has the undeniable virtue that the anode slime on the one hand, and the precipitated cation on the other hand, are separated beyond the possibility of mixing; and the analytical determination of the weight of the cathode precipitate is certain and easy. For this reason alone it was first suggested by Poggendorff long ago; he had no inkling of the peculiar nature of the anolyte.

In the next place, the Harvard results of 1902, comparing this coulometer with other forms, (especially with the inverted wire-gauze form), seem to show indubitably that no important amounts of anode liquid escape from inside the cup into the catholyte. In order that the cup should thus be effective, it is important, of course, that there should be no large orifices in it, and that the level of the liquid within it should always be distinctly lower than that outside. Thus, if any diffusion takes place, it must be essentially from the outside inward. The cup must be very fine-grained

¹ *Phys. Rev.*, 10, 169 (1900).

² *Loc. cit.*, Richards and Heimrod, *Proc. Am. Acad.*, 37, 420 (1902).

and the absence of large holes should be tested, both by the rate of flowing from such a cup when filled with liquid and hanging in the air, as well as by causing air to be delivered through it under water. If in the latter case considerable pressure is needed, and the air escapes in a multitude of very fine bubbles from the whole surface, the cup is suitable for the purpose. If the delivery is easy, and if one point claims most of the outflow, the cup should be rejected.¹

It is, of course, possible that a trace of the offending complex ion, or whatever the compound may be which bears the surplus of silver, may be carried *electrolytically* through the cup, but there is good reason to believe from the quantitative results already quoted that this amount is so small as to be taken care of by the dissolved oxygen in the outside electrolyte before it can reach the cathode.

At any rate there can be no question that the porous cup coulometer gives very constant results. Even those who deny the necessity of its use grant this claim; and, indeed, the results of all three National Bureaus, as well as Hulett's (if we assume that under like conditions the inclusions are nearly constant), prove its constancy.

The chief objection which has been raised to the cup is the possibility that it may introduce impurities into the electrolyte. This it will do, of course, if it has not been properly cleaned. Neither an excess of acid nor an excess of alkali nor cyanide should remain in it. We believe, however, that if made of good insoluble porcelain it can cause no important impurity in the solution when it has been properly cleaned with nitric acid, thoroughly washed with water and soaked in silver nitrate solution. Moreover, it must be cleaned before every determination if an accurate result is desired. The glazing of the cup upon its upper portion, unless filling every pore, seems to be of doubtful efficacy because of the difficulty of washing out acid or other impurity which may penetrate upwards beneath the glaze.² We have found by experimental evidence that a porous cup blackened by exposure to light and dust is capable of yielding too high a deposit. In our experiments recounted above, the cups were cleaned, of course, with the greatest care, and washed until they were certainly free from acid. Ignition after such washing should not be practiced, as it alters the condition and increases the solubility of the porous silicate. Careful tests of our own—not only those described above, but also others in which the silver nitrate in cups which had been soaked were tested with permanganate—showed that our porous cups had no reducing action upon silver nitrate.

The only important difficulty which we have encountered in our own work with the porous cup is the fact that the coulometer containing such

¹ Richards and Cox, *THIS JOURNAL*, 26, 822 (1914).

² Buckner and Hulett, *loc. cit.*, pp. 371 and 380.

a cup changes its resistance somewhat as the deposit proceeds. This is more or less the case with any form of coulometer, except the inverted wire-gauze form, and in the porous cup coulometer the trouble may be minimized by keeping the levels inside and out constant by means of automatic syphons. Attention should be directed to the importance of taking the liquid from the very bottom of the anode cup, because this is where the heavy anode liquid accumulates.

Of course, nothing in this paper or the preceding paper should be construed as pretending to state the exact quantitative effect either of inclusion or of the anode liquid on any of the preceding investigations of others. So many circumstances, either already known or as yet undetermined, seem to decide the amounts of these respective effects that they can be estimated only under the special conditions present in each particular case, and cannot be exactly determined by a subsequent examination of the printed record. It may well be that some of the eminent investigators, whose work we have mentioned, have really had in their precipitates a smaller amount of inclusion, and (with the Kohlrausch instrument) a smaller anode effect than we have found in our experiments. We earnestly hope that they will determine the presence or absence of these disturbing circumstances by methods such as have been used in the present research, or by other adequate methods, so that all doubts may be removed. Especially as regards the electrochemical side of the matter this is important. Here a *constant* value for the faraday is not enough—the weights must represent the amount of pure substances chemically equivalent. The importance of this condition was seen by the Bureau of Standards as well as at Harvard in the consideration of the iodine-silver voltameter of Bates and Vinal, discussed in our previous paper.

It is to be hoped, also, that some form of precise coulometer may be found for general use, which will not involve precautions so elaborate as those recommended by some of the recent experimenters; for these are beyond the reach of many chemists and physicists. The outcome of the present research leads us to believe that results obtained by igniting the deposit in the porous cup coulometer give not only the most accurate values for electrochemical comparison, but also the safest and most easily attained standard values for the measurement of current. Perhaps when all the manifold subtle influences which determine inclusion are thoroughly known, a better way may be found; the conviction just expressed is of course based upon the actual experience up to the present time.

Because the discussion of our experiments has inevitably involved emphasis upon certain omissions in the work of other experimenters, we are especially desirous to call attention here to the real services to science rendered by them, particularly by the two series of researches

which have added most to the knowledge of the subject during the last few years.

Rosa and Vinal of the Bureau of Standards have proved, in confirmation of the early tentative Harvard results, that *under perfectly constant conditions* the porous cup coulometer, even when not ignited, gives very constant deposits. This was the main question which their careful investigation sought to answer. They have further demonstrated that certain organic impurities, including filter paper, cause striated deposits, that the contamination of the electrolyte by filter paper increases the weight of the deposit dried at 160° , that acid diminishes this weight, and that large and small unignited coulometers give lower and more nearly equal results when the electrolyte is very pure. They have presented an interesting hypothesis capable of explaining many of these varied phenomena and exhibit excellent photographs of the striations. Although they have done little concerning the anode liquid, fortunately their lack of study of this aspect of the question has had no great practical effect on their results, because for all their chief experiments they wisely used the porous cup coulometer, in which the effect of the anode liquid is nullified.

Hulett and his collaborators at Princeton have published an interesting series of carefully obtained results, which seem to us to afford valuable support for the following outcomes of the early Harvard work: First, that the inclusions are variable under varying circumstances and often important in amount, even when the electrolyte is of a high degree of purity; and, secondly, that the anode liquid, independent of organic matter, may augment unduly the weight of the cathode. They have further made careful analyses of the chemical nature of the inclusions, showing them to consist (as had been expected) chiefly of an aqueous solution of silver nitrate. Many other matters of detail were also carefully studied by them, especially the effects caused by the presence of different gases. The recent experiments of Hulett and Vinal on the solution of silver in water, when in contact with platinum, are especially interesting.

Each of these series of investigations must be carefully studied by subsequent workers, for each contains the account of well executed experimentation concerning important aspects of the subject.

As has been already pointed out, the results and conclusions recorded in our two new papers, while in no way inconsistent with the results and conclusions just mentioned in detail, have differed in other particulars from those of these eminent investigators and of several other investigators in this field. Although there has been much private correspondence between most of those concerned during the last few months, we find no reason to alter our opinions about the main points at issue. Nevertheless, we prefer at this time to forego further discussion of these differences, especially because several of the investigators (including

one of us) are continuing their studies. The large number of variables which modify the precise working of the coulometer has led in the past to unfortunate confusion; but we hope that unanimity may before long be attained, and that the outcome of the present research may ultimately be of service in the attainment of this common point of view.

In conclusion, we wish once more to advocate strongly the use of the scientifically derived and logical name "coulometer" for this instrument, when it is used to determine accurately the number of coulombs of electricity in physical or chemical experimentation, in place of the vague and inaccurate term "voltmeter." This latter was devised before the dimensions of electrical energy were understood, and is at present an anachronism. We feel that we are second to none in the desire to do homage to the incomparable genius of Faraday; but we cannot see how the retention of this antiquated and confusing name can, in any way, enhance his credit.

We are glad to express our indebtedness to the Carnegie Institution of Washington for much of the apparatus used in this research.

Summary.

In the previous paper we have shown in verification of the early Harvard work that the inclusion of mother liquor by a silver precipitate may vary according to circumstances from 0.004 to at least 0.03% of the weight of the precipitate, and hence should be determined in each case.

In that paper we also emphasized the importance of obtaining a definite knowledge concerning the amount of imprisoned electrolyte before conclusions are drawn from the weight of the deposit.

In the present paper it is shown experimentally, confirming our earlier results and those of Hulett, that the anode liquid may really augment the weight of the ignited cathode deposit, even when no filter paper is present. This effect is presumably due to metastably dissolved silver, in the form of an argentous ion but the mechanism of the effect is not yet fully elucidated.

The Kohlrausch coulometer, although an improvement over the filter paper form, was found in our experiments not to remove all of this trouble.

An illusory agreement between different forms of coulometer was found in some of our uncorrected experiments, because of the balanced effect of the two errors (inclusion and surcharge of silver). By comparing the weights of the ignited precipitates, this compensating effect could be detected and analyzed.

The best results were produced by the use of a small porous-cup coulometer with a highly burnished cathode and pure electrolyte, the deposit being ignited at incipient redness.

These and other questions concerning the coulometer are being yet further experimentally investigated at this Laboratory.

THE IONIC HYDRATION AND TRANSFERENCE NUMBERS OF CAESIUM CHLORIDE.¹

BY EDWARD W. WASHBURN AND EARL B. MILLARD.

Received January 25, 1915.

1. Outline of the Investigation.

In a previous investigation by one of the authors² the transference numbers and relative ionic hydrations of the chlorides of lithium, sodium and potassium in 1.2 *M* aqueous solution at 25° were measured by means of transference experiments in the presence of a suitable nonelectrolyte as a reference substance. The object of the present investigation was to extend these data so as to include caesium chloride, since there was much reason to believe that caesium ion is the least hydrated of all the alkali ions and there was the interesting possibility that it might be so little hydrated that the water transference would take place from cathode to anode. The previous work with sodium chloride was repeated and attempts, only partially successful, were made to include the alkali nitrates in the investigation also.

2. Purification of Materials.

Raffinose.—The raffinose was purified by recrystallization as described by Washburn and Williams,³ until a 0.1 *M* solution of the crystals had a specific conductance of less than 3×10^{-6} reciprocal ohms at 25°.

Caesium Chloride.—Part of the raw material consisted of 700 g. of polucite containing about 35% of caesium. The caesium extracted from this mineral was mixed with some caesium salts obtained from various dealers and the whole subjected to purification by recrystallization of the dichloriodide.⁴ The final product was tested with a spectroscope and found to be free from all other alkali metals except a faint trace of sodium arising from the glass vessels used as containers.

Incidentally it was found that prolonged boiling of a caesium chloride solution does not result in the volatilization of even a trace of the salt, which is contrary to a statement made by Bailey⁵ that caesium chloride is volatile with steam.

3. Apparatus and Method of Procedure.

The transference apparatus, the method of carrying out the transference experiments and the analytical methods were identical with

¹ Part of a thesis submitted by Earl Bowman Millard to the Graduate School of the University of Illinois in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1914.

4. Notation.

d_4^{25}	specific gravity of the solution at 25° referred to water at 4°.
P_r	percentage of reference substance in solution.
P_s	percentage of the electrolyte in the solution.
Ag	grams of silver deposited in the coulometers.
m^e	total mass in grams of electrode portion.
$\Delta m_w, \Delta n_w$	increase in grams (or mols) of water in the electrode portion.
$\Delta m_s, \Delta n_s$	increase in grams (or mols) of electrolyte in the electrode portion, referred to raffnose.
$\Delta m_s, \Delta n_s$	increase in grams (or mols) of electrolyte in the electrode portion, referred to <i>water</i> .
N	equivalents of electricity passed through the solution.
T^e, T^a	true transference number of the cation (or anion) calculated on the assumption that the raffnose remains stationary during the passage of the current.
T_H^e, T_H^a	ordinary or Hittorf transference number.
Δn_F^e	number of mols of water transferred from anode to cathode per faraday of electricity.
A	anode portion.
M_a, M, M_c	anode middle, middle, cathode middle portions.
C	cathode portion.

5. Data and Results with Sodium Chloride Reference Substance—Raffnose.

Composition of the solution:					
Sodium chloride 1.12 formula weights of NaCl per 1000 g. of water.

those employed in the previous work and need not be described again.

The polarimeter employed for determining the concentration of the raffinose was a better and more accurate instrument than the one employed in the previous work and it was largely due to this fact that conclusive and satisfactory results were obtained with caesium chloride, the water transference being so small in amount, that a very high degree of accuracy was necessary in the polarimetric readings in order to measure its magnitude. The instrument was a triple field Schmidt and Haensch polarimeter of sufficient size to enable the use of a 100 cm. jacketed observation tube. In this tube all the solutions employed were polarized. The light was furnished by a quartz mercury vapor lamp, and was further purified by passing it through a spectroscope. The green mercury E-line was the one employed and this fact also contributed to the increase in the degree of accuracy over that obtained in the previous investigation, since the specific rotatory power of raffinose for the E-line is $[\alpha]_E = 144.55^\circ$ as against $[\alpha]_D = 123.00^\circ$ for the D-line.¹ The addition of 1.2 mol of caesium chloride to a liter of the raffinose solution was found to increase the specific rotatory power to $[\alpha]_E = 144.64$ which is the same increase as that produced by potassium chloride.

The experimental data and results are shown above.

7. Results with Potassium Nitrate.

Several runs were made on 1.2 *M* potassium nitrate solution in the presence of 0.08 mol of raffinose, using a silver chloride cathode and rejecting the anode side altogether. Membranes of silk gauze were inserted in the connecting tubes of the stopcocks and a cooling coil was used at the cathode side to increase the density of this portion, in an effort to prevent mixing. In every experiment, however, chloride was found in the middle portions, indicating that mixing had taken place. On account of this mixing it did not seem worth while to complete the analyses. In one case, however, the solutions were analyzed, and it was shown that the ratio of raffinose to water had decreased at the cathode. In other words, the potassium ion carries water with it to the cathode in a potassium nitrate solution or, if one wishes to ascribe the change in the raffinose-water ratio to a complex formed between the chloride ion and the raffinose, then a similar complex must also be assumed in the case of the nitrate ion.

8. Comparison of Degrees of Hydration of the Ions.

For purposes of comparison the transference and hydration data for the four alkali chlorides and hydrochloric acid are summarized in Table I.

¹ Bates, *Bureau of Standards Bulletin* 2, 239.

TABLE I.¹

Electrolyte (Conc. 1.3 N).	n_w^F/T^c	Δn_w^F	T^c	T_∞^c	T_H^c
HCl.....	0.28 \pm 0.04	0.24 \pm 0.04	0.844	0.821	0.82
CsCl.....	0.67 \pm 0.1	0.33 \pm 0.06	0.491	0.491	0.485
KCl.....	1.3 \pm 0.2	0.60 \pm 0.08	0.495	0.495	0.482
NaCl.....	2.0 \pm 0.2	0.76 \pm 0.08	0.383	0.396	0.366
LiCl.....	4.7 \pm 0.4	1.5 \pm 0.1	0.304	0.330	0.278
	$N_w^H = 0.28 \pm 0.04 + 0.185 N_w^{Cl}$ (1)				
	$N_w^{Cs} = 0.67 \pm 0.1 + 1.03 N_w^{Cl}$ (2)				
	$N_w^K = 1.3 \pm 0.2 + 1.02 N_w^{Cl}$ (3)				
	$N_w^{Na} = 2.0 \pm 0.2 + 1.61 N_w^{Cl}$ (4)				
	$N_w^{Li} = 4.7 \pm 0.4 + 2.29 N_w^{Cl}$ (5)				

The values of the true transference number of the cation in 1.2 *M* solution (T^c) and at infinite dilution (T_∞^c) as well as the ordinary Hittorf number (T_H^c) appear in the first part of the table. In the second part of the table N_w indicates the average number of water molecules carried by the ion (indicated by the superscript) as it moves through the solution. From Equations 2 and 5 we obtain the relation,

$$N_w^K - N_w^{Cs} = 0.65,$$

or in words, the caesium ion carries on the average 0.65 less molecules of water than the potassium ion and is, therefore, the least hydrated of the alkali ions. If we assign to the chloride ion the hydration values (1) zero and (2) four molecules, the corresponding hydration values for the other ions are shown in Table II.

TABLE II.

N_w^{Cl-}	N_w^{H+}	N_w^{Cs+}	N_w^{K+}	N_w^{Na+}	N_w^{Li+}
0	0.3	0.7	1.3	2.0	4.7
4	1.0	4.7	5.4	8.4	14.0

All of the data given above are, of course, based upon the assumption that the raffinose remains absolutely stationary during the passage of the current. There is thus far no evidence indicating that this assumption is invalid to an extent which would appreciably affect the results. With the polarimetric apparatus at present at our disposal it will be possible to work with considerably smaller salt concentrations and also to reduce the concentration of the reference substance as low as 0.01 *M* in the case of lithium chloride solutions. By substituting trehalose for raffinose it will probably even be possible to use a considerably lower concentration than this and thus to remove all reasonable doubt as to the validity of the assumption in question. Work along these lines will be continued in this laboratory.

¹ In this table the values given are the *means* of the two results obtained at each electrode independently.

9. Summary.

1. By transference experiments in the presence of raffinose as a reference substance, the true transference number of caesium ion in 1.2 *M* caesium chloride solution at 25° has been found to be 0.491 and the water transference 0.33 \pm 0.06 formula weights of H₂O per faraday, from anode to cathode. Caesium ion is thus the least hydrated of the alkali ions. It carries on the average 0.65 mol less H₂O than potassium ion.

2. Similar experiments with potassium nitrate solutions showed that the water transference was from anode to cathode with this salt also.

3. The effect of caesium chloride upon the specific rotatory power of raffinose is the same as that of potassium chloride. It increases $[\alpha]_D$, 0.09° per mol of salt added to a liter of the 0.1 *M* raffinose solution.

4. Contrary to a statement in the literature, caesium chloride is not appreciably volatile with steam.

URBANA, ILL.

[LABORATORY OF PHYSICAL CHEMISTRY, UNIVERSITY OF WISCONSIN.]

THE HEAT OF NEUTRALIZATION OF HYDROXYLAMINE AND TETRAMETHYLAMMONIUM HYDROXIDE.

By EMIL O. ELLINGSON.

Received January 29, 1915.

Recent thermochemical measurements by Richards and his co-workers, using the adiabatic calorimeter, have shown conclusively that many of the thermochemical data in the literature are of very questionable accuracy. The adiabatic calorimeter permits a degree of accuracy heretofore unattainable in thermochemical measurements and for the first time puts these measurements on a par with the measurements of other physicochemical constants. Since considerable of the thermochemical data in the literature have been determined by but two investigators (Berthelot and Thomsen), and as the data are often the results of single measurements, by methods which at best could give only approximate values, it has seemed highly desirable that these measurements be repeated, using the methods for precise calorimetry now available.

This paper deals with the measurement of the heat of neutralization of hydroxylamine and tetramethylammonium hydroxide when neutralized with hydrochloric, sulfuric, and trichloroacetic acids in aqueous solutions, using an adiabatic calorimeter. The method followed was practically the same as that used by Richards and Rowe,¹ and the adiabatic bath employed was similar to the one designed by Richards and Burgess² and by Richards and Jesse.³

Materials.

Trichloroacetic Acid.—A well-known manufacturer's purest trichloroacetic acid was used. The sample taken for the experiments showed but the slightest trace of hydrochloric acid.

Tetramethylammonium Hydroxide.—This base was prepared from recrystallized tetramethylammonium iodide by dissolving the latter in pure water and agitating the solution for several hours at about 45°, with an excess of freshly precipitated silver oxide, avoiding contact with air as much as possible. The warm solution was filtered quickly by powerful suction, through a layer of several filter papers, directly into the container designed for the base. The hydroxide was then carefully standardized by titration with a standard solution of sulfuric acid, using methyl orange as indicator.¹ The strength of the sulfuric acid solution had previously been determined by careful gravimetric analyses.

Hydroxylamine.—Freshly prepared hydroxylamine was used exclusively. The base was made from dry hydroxylamine phosphate $[(\text{NH}_2\text{OH})_3\cdot\text{H}_3\text{PO}_4]$ by distilling the latter at a low pressure, according to the method of Uhlenhuth.² In this distillation 20 g. of the salt were heated in a fractionating bulb at about 20–30 mm. pressure. The salt decomposed into phosphoric acid and hydroxylamine, the base passing over into the ice-cooled receiver where it solidified. The fraction distilling between 90° and 130° at about 25 mm. pressure was used.

Since hydroxylamine is explosive at higher temperatures, it is necessary to take proper precautions during the distillation.

Strength of Solutions.

Generally the solutions were made up to a concentration approximating, in some cases, to the ratio of one mol of the reagent to fifty of water, and, in other instances, to the ratio of one to two hundred.

Trichloroacetic Acid.—The acid was dissolved in pure, distilled water and the solutions were made up to the desired strength, guided by titration against a standard solution of sodium hydroxide, using methyl orange as indicator.

Hydroxylamine.—The crystalline hydroxylamine, obtained from the decomposition of hydroxylamine phosphate $[(\text{NH}_2\text{OH})_3\cdot\text{H}_3\text{PO}_4]$, was dissolved in pure, cold water immediately upon the completion of the distillation. The solutions were then made up to the required strength, as indicated by titration against a gravimetrically standardized solution of sulfuric acid, using methyl orange as indicator. The solutions were kept in ice because the base decomposes slowly at the ordinary room

¹ The base exhibited no apparent change of strength on standing for a considerable time, as was indicated by its titration, in the same manner, five months after the experiments herein described were performed.

² *Ann.*, 311, 117 (1900).

temperature. The calorimetric measurements were, therefore, made as soon as possible after standardization of the solutions.

Tetramethylammonium Hydroxide.—The strength of the solution of this base was obtained by titration as previously stated, and the hydroxide was kept in a receptacle adapted to prevent atmospheric carbon dioxide from coming in contact with it.

Method and Apparatus.

The thermal data were obtained in exactly the same manner as described by Mathews¹ in his experiments on the adiabatic measurements of heats of reaction in nonaqueous solutions. The accompanying diagram represents in cross-section the essential parts of the apparatus. The adiabatic bath D and the necessary fixtures were adjusted in identically the same way as were the corresponding parts of the apparatus used by Mathews.

A weighed quantity (of a known volume) of the solution of the base to be neutralized was placed in the platinum bottle A, which was suspended in a known weight of water contained in the platinum calorimeter B. The quantity of acid required to exactly neutralize the alkali (plus a predetermined amount necessary to compensate for the wetting of the walls and for loss on drainage) was placed in the jacketed, cylindrical compartment C, from which it could be run into A through a stopcock. The acid in C and the base in A were stirred, the former by means of a heavy platinum spiral surrounding the thermometer J, and the latter by a platinum stirrer, P. The water in B was stirred by a silver stirrer, H, attached to two hard-rubber rods. A standardized Beckmann thermometer, I, which could easily be read to 0.001° by the aid of a sliding telescopic lens, was placed in B to register the rise in temperature of the water in the calorimeter. In order that the acid and alkali might be at the same temperature at the time of mixing, the pump E was used to force a strong current of the alkali solution in D through the jacket, L. As the Beckmann thermometer J had previously been carefully compared with the standardized thermometer I, it was possible to determine when the temperatures of the acid and the base were precisely the same, by referring to the table of comparison. The Beckmann thermometer I had been standardized very accurately, in the adiabatic calorimeter, against a thermometer standardized by the Bureau of Standards.

When the acid and the alkali had reached exactly the same temperature, they were quickly mixed by allowing the acid in C to run into the alkali in A, the last drop in the delivery tube of C being forced out by a quick compression of the rubber bulb M. As the temperature in B began to rise, the temperature of the bath D was made to rise by running

¹ THIS JOURNAL, 33, 1291 (1911).

concentrated sulfuric acid from the buret N into the alkali. The flow was so controlled that the temperature in D, as indicated by its thermometer, was always equal to that in B, as shown by the thermometer I.

The solution in D was stirred very thoroughly by a powerful stirrer, O. The stirrers and pump were run by an electric motor at a definite speed throughout all the experiments. The platinum calorimeter B was supported within a closed copper vessel by means of dry cork points, thus avoiding direct contact with the surrounding bath.

In order to calculate the water equivalent of the salt solution resulting from the reaction, the bottle A, with its contents, was weighed after each experiment to ascertain the exact weight of the salt solution. The water equivalent of the solution was then computed from its weight and specific heat, the latter value having been obtained previously by adiabatic measurements.

In every experiment the amount of acid required for the exact neutralization, plus a certain excess to make up for the loss of liquid adhering to the walls of compartment, C, was determined before the actual measurement was made.

TABLE I.

Heat evolved by the neutralization of 40.77 g. of 1.354 *N* hydrochloric acid (gravimetrically standardized) by 2.71 *N* sodium hydroxide.

Initial temp. (cor.) of the NaOH in C and of the HCl in A (of the calorimeter).....		18.159°
Final temp. of the calorimeter (cor.).....		19.606°
Rise in temperature.....		1.447°
Water in the calorimeter.....		450.00 g.
Wt. of the platinum calorimeter B	100.73 g.	
Water equivalent of calorimeter B	$= 100.73 \times 0.0324 =$	3.264 g.
Wt. of the platinum bottle A	52.436 g.	
Water equivalent of bottle A	$= 52.436 \times 0.0324 =$	1.699 g.
Wt. of the silver stirrer H	23.876 g.	
Water equivalent of stirrer H	$= 23.876 \times 0.055 =$	1.313 g.
Wt. of the platinum stirrer P	7.831 g.	
Water equivalent of stirrer P	$= 7.831 \times 0.0324 =$	0.254 g.
Water equivalent of thermometer I =		2.163 g.
Total water equivalent of the calorimeter and fittings.....		8.693 g.
Water equivalent of the 63.02 g. of NaCl solution formed, sp. ht. being 0.95 ¹		59.87 g.
Total water equivalent = (450 + 98.693 + 59.87) =		518.563 g.
Total heat evolved by the reaction =		
518.56 \times 1.447 =		750.35 cal.

The results given in Table II are taken from four experiments conducted to determine the heat liberated as shown in Table I.

TABLE II.

Total water equivalent.	Initial temp. of acid and base (cor.).	Rise in temp. (cor.).	Total heat liberated.
518.56	18.159°	1.447°	750.35 cal.
518.59	19.521°	1.446°	749.88 cal.
518.61	20.203°	1.446°	749.91 cal.
518.54	18.462°	1.447°	750.32 cal.

Average, 750.12 cal.

Hence, by exactly neutralizing 40.77 g. of 1.354 *N* hydrochloric acid by 2.71 *N* sodium hydroxide 750.12 calories of heat are evolved.

¹ Thomsen's value for the specific heat.

TABLE III.

The specific heat of hydroxylamine sulfate $[(\text{NH}_2\text{OH})_2\text{H}_2\text{SO}_4]$ solution formed by the neutralization of 30.22 g. of 1.0578 *N* hydroxylamine by 1.0607 *N* sulfuric acid. (The approximate molecular ratio of the base or acid to water was 1:50.)

Wt. of 1.354 <i>N</i> hydrochloric acid.....	40.77 g.
Excess of NaOH solution taken.....	0.07 cc.
Wt. of the hydroxylamine sulfate solution placed in the calorimeter.....	450.00 g.
Initial temp. (cor.) of the NaOH in C and of HCl in A (of the calorimeter).....	18.535°
Final temp. of the calorimeter (cor.).....	20.049°
Rise in temperature.....	1.514°
Water equivalent of the 62.96 g. of NaCl solution formed (sp. ht. 0.95) ¹	59.81 g.
Water equivalent of the calorimeter and fittings (Table I).....	8.69 g.
Total water equivalent.....	68.50 g.
Total heat absorbed exclusive of the hydroxylamine sulfate solution = 68.50×1.514	103.71 cal.
Heat liberated by the neutralization of 40.77 g. of 1.354 <i>N</i> hydrochloric acid (Table II).....	750.12 cal.
Therefore, the total heat taken up by the hydroxylamine sulfate solution = $750.12 - 103.71 = 646.41$ cal.	
Specific heat of the solution = $646.41 \div (450 \times 1.514) = 0.9488$	

TABLE IV.

Heat evolved by the neutralization of 30.22 g. of 1.0578 *N* hydroxylamine by 1.0607 *N* sulfuric acid. (The molecular ratio of base or acid to water was approximately 1:50.)

Wt. of hydroxylamine taken.....	30.22 g.
Wt. of sulfuric acid used.....	30.98 g.
Initial temp. (cor.) of the sulfuric acid in C and of the hydroxylamine in A (of the calorimeter).....	18.464°
Final temp. of the calorimeter (cor.).....	19.169°
Rise in temperature.....	0.705°
Water in the calorimeter.....	450.00 g.
Water equivalent of the 61.21 g. of hydroxylamine sulfate solution formed, sp. ht. 0.9488 (Table III).....	58.08 g.
Water equivalent of the calorimeter and fittings.....	8.69 g.
Total water equivalent.....	516.77 g.
Heat evolved by the reaction = $516.77 \times 0.705 = 364.32$ cal.	
Since the 30.22 g. of hydroxylamine solution measured 30.08 cc. (at 20°), this amount of heat was liberated by neutralizing $30.08/1000 \times 1.0578 \times 33$ or 1.05 g. of the base in the given concentration. The heat evolved by the neutralization of 1 g. molecule of hydroxylamine will, therefore, be $364.32 \times 33/1.05 = 364.32 \times 31.43 = 11450.5$ cal.	

The calorimetric procedure consisted in first finding the amount of heat evolved in the neutralization of a definite weight of a certain hydrochloric acid solution by a certain sodium hydroxide solution, the strength

¹ Thomsen's value.

of both being known, using a known weight of water in the calorimeter. This identical reaction was repeated, quantitatively, whenever it was desired to use it as a source of a definite, known amount of heat in measuring the specific heat of the salt solution which was formed in the process of any given neutralization. The water equivalent of the calorimeter and fittings was calculated from the heat capacities of the several parts. The water equivalent of the sodium chloride solution resulting from the neutralization was computed, using Thomsen's value for the specific heat of sodium chloride solution at the given concentration and temperature.

TABLE V.

Results of the measurements of the specific heat of the salt solution formed in the bottle A during the various neutralizations. In each of these determinations 450 g. of the salt solution in question were placed in the calorimeter.

The second step concerned itself with the measurement of the heat liberated when neutralizing a definite weight of a given base by a certain acid, the exact strength of each solution being known, and the same amount of water being placed in the calorimeter as before. Since a knowledge of the water equivalent of the salt solution formed in any neutralization was indispensable, it became necessary to measure the specific heat of such solution.

Hence the third step consisted in measuring the specific heat of the salt solutions formed. This value was obtained by substituting, in the calorimeter, an equal weight of the salt solution in question for the water originally used in it, and then repeating the neutralization of the hydrochloric acid with the sodium hydroxide to liberate an exact, known amount of heat as described above.

The preceding results are given to illustrate the method and calculation involved (Tables I, III, IV).

The final data for the heat liberated by the neutralization of solutions of hydroxylamine and tetramethyl ammonium hydroxide by solutions of hydrochloric, sulfuric, and trichloroacetic acids are tabulated in Table VI.

It will be noticed, in Table VI, that the heat of neutralization of a given base decreases considerably with the increase in the dilution of the solutions. Thus, the heat evolved when hydroxylamine acted on hydrochloric acid, in a molar concentration of 1 to 50, was 191 calories higher than when the reaction took place in a concentration of 1 to 200. Similarly, when the same base acted on sulfuric acid, in a concentration of 1 to 50, 374 calories more were liberated than when the reaction occurred in a concentration of 1 to 200. Again, when this base was neutralized by trichloroacetic acid, in the ratio of 1 to 100, 401 calories more were given off than when the neutralization took place in the ratio of 1 to 200. The table also shows that the heats of neutralization of trichloroacetic and hydrochloric acids with a given base were approximately the same for the dilution of 1 to 200. For convenience in comparing these results Table VII is given. The corresponding values obtained by Thomsen are given in brackets.

TABLE VII.

The thermal effect due to a definite amount of dilution in the sulfate

was nearly twice that produced in the chloride by the same amount of dilution, whereas the thermal change in the trichloroacetate, caused by a dilution only half as great, was considerably larger than that brought about in the sulfate.

The values for the heats of neutralization of hydroxylamine are approximately the same as Thomsen's, our figures ranging from 0.3% to 2.6% higher. In the case of tetramethylammonium hydroxide, however, the values obtained are about 7.5% lower than Thomsen's. No data on the heats of neutralization of the two bases with trichloroacetic acid have been found in the literature for comparison.

The results recorded in this paper are believed to possess an unusually high degree of precision, and yet, such results are to be expected from the exact method of calorimetry employed.

Summary.

1. The heats of neutralization of hydroxylamine and tetramethylammonium hydroxide when neutralized by hydrochloric, sulfuric, and trichloroacetic acids, in aqueous solutions, have been measured adiabatically.

2. The results obtained for hydroxylamine are from 0.3% to 2.6% higher and for tetramethylammonium hydroxide about 7.5% lower than Thomsen's values for the same bases (Table VII).

3. The heats of neutralization of hydroxylamine and tetramethylammonium hydroxide with trichloroacetic acid have been measured for the first time, as far as we are aware.

In conclusion the writer wishes to express his obligation to Professor J. H. Mathews for helpful suggestions as well as for aid in obtaining the apparatus used.

MADISON, WIS.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF BRYN MAWR COLLEGE.]

A CRITICISM OF THE ELECTRON CONCEPTION OF VALENCE.

By ROGER F. BRUNEL.

Received January 18, 1915.

Physical investigations of recent years have convinced most chemists that atoms of all elements contain, if they are not made up of, negative electrons, held in position by a positive charge. The attractive force between atoms is thus electrical in origin. This view is shared by the author.

In 1909, Nelson, Beans, and Falk¹ published an article developing the idea that "every chemical bond formed between two atoms involves the transfer of a corpuscle from one atom to the other,"² a conception for which

¹ *School Mines Quart.*, 30, 179 (1909).

² *THIS JOURNAL*, 35, 1810 (1913).

J. J. Thomson¹ was originally responsible, although he has now abandoned it. The resulting electrostatic charges are apparently considered responsible for the interatomic attraction. This conception is now commonly referred to in *THIS JOURNAL* as the "Electron Conception of Valence," and has been extensively developed by Nelson, Beans, and Falk, Fry, L. W. Jones and others.² According to this hypothesis chemical bonds are to be represented as $\text{Cl} \longrightarrow \text{Cl}$, $\text{C} \longrightarrow \text{C}$, $\text{H} \longrightarrow \text{Cl}$, or $\text{Cl} \overset{+}{\text{---}} \overset{-}{\text{Cl}}$, etc. This hypothesis is by no means generally accepted, as is the fundamental conception of the electrical constitution of the atom, and is by no means a necessary corollary of that.

Objections to this conception from the physical point of view, all of which appear to the author to be valid, have recently been brought forward by Bates.³ Bray and Branch,⁴ Lewis,⁵ and Arsem,⁶ have recently proposed other hypotheses dealing with the same question, and Thomson⁷ now offers quite a different explanation of the manner of chemical union. Some of these views will be referred to further below. The object of this paper is to call attention to certain weaknesses in the arguments put forward in support of this conception and certain difficulties that arise in applying it to chemical phenomena.

The development and application of this conception have involved the formulation of several supplementary hypotheses, and we must turn to the earlier papers on the subject for direct arguments, based on simple phenomena, for the fundamental assumption on which it is based. I would first call attention to certain of these arguments, advanced by Nelson, Beans, and Falk.⁸

(a) These authors note that according to their hypothesis ethane must have the unsymmetrical structure $\text{H}_3\text{C} \overset{+}{\text{---}} \overset{-}{\text{CH}_3}$. To meet the objections likely to be called forth from the organic chemist by such an assumption, it is stated that one substance, triphenylmethyl, shows evidence of such a polar structure in that it forms a conducting solution in sulfur dioxide, where these authors assume that the ions $(\text{C}_6\text{H}_5)_3\text{C}^+$ and $(\text{C}_6\text{H}_5)_3\text{C}^-$ are present.

In the first place this assumes one of the points at issue, for the ad-

¹ *Phil. Mag.*, [6] 7, 237.

³ *THIS JOURNAL*, 36, 789 (1914).

⁴ *Ibid.*, 35, 1440 (1913).

⁵ *Ibid.*, 35, 1448.

⁶ *Ibid.*, 36, 1655.

⁷ *Phil. Mag.*, [6] 27, 757 (1914).

⁸ *School Mines Quart.*, 30, 179 (1909). Practically the same arguments are to be found in *THIS JOURNAL*, 32, 1637 (1910).

vocates of the theory have first to offer proof that the ability of a substance to split into charged ions in solution is evidence that the dissociating parts are already charged in the molecule before dissociation occurs.

But, furthermore, there is little evidence that the ionization of triphenylmethyl is of the sort indicated, the present tendency being, in the case of nonaqueous solvents at least, to assume the ionization of some complex formed with the solvent. Gomberg¹ assumed that triphenylmethyl ions are present in sulfur dioxide solution, but with no direct evidence except that he noted the similarity between this case and the formation of conducting solutions of bromine in various solvents, especially in sulfur dioxide. Such an argument loses its force in view of the recent investigations of Bruner and Galecki,² and Bruner and Bekier,³ who obtained evidence that in solutions of bromine, and iodine, ICl and ICl₃, in nitrobenzene and sulfur dioxide no halogen kations are present.

Schlenck⁴ has also shown that although triphenylmethyl sodium forms a conducting solution in ether, it cannot be due to dissociation in the sense $(C_6H_5)_3C^+ + Na$, but rather to the ionization of some more complex molecules formed in the solution.

The ionization in these cases is thus of a more complex sort than at first appears, and at the present stage of our knowledge of such phenomena can hardly furnish proof that in sulfur dioxide solution of triphenylmethyl we have the ions assumed by Nelson, Beans, and Falk. In general, we can certainly say that in organic compounds there is not the slightest evidence of such polarity as is demanded by this theory on the part of the carbon atoms.

(b) The next use made of the directed valences is in explaining the well-known fact that the melting points of the homologous series of $\omega\omega'$ saturated dibasic acids fall on a zigzag curve, those of alternate members of the series being lower than those of the preceding and following members. An explanation is proposed which is based on the presence of similar groups at the ends of the carbon chain. This results in alternate symmetrical and unsymmetrical valence structures for the members of the series, which might be responsible for alternate high and low melting points. These authors suggest that the same may be found to hold true for the series of monobasic acids, for which, they remark, the electronic formulas cannot yet be written. The last remark is not particularly convincing, since it would appear that we know as much about the monobasic acids as about their more complex dibasic relatives. The fact that the melting points

¹ *Ber.*, 37, 2050 (1904).

² *Z. Physik. Chem.*, 84, 513 (1913).

³ *Ibid.*, 84, 570.

⁴ *Ber.*, 47, 1678 (1914).

of the monobasic acids do fall on a zigzag curve¹ exactly similar to that for the dibasic acids appears to invalidate the argument for the "electron conception valence" based on the latter, since the explanation proposed for the dibasic acids rests fundamentally on the presence of similar groups at both ends of the carbon chain and would demand a smooth curve for the monobasic acids.

Furthermore, if we examine other homologous series we find, in as far as data are available in the latest edition of the Richter Lexikon, similar zigzag melting point curves for the ethyl esters of monobasic acids, for the amides of dibasic acids, and for the $\omega\omega'$ -glycols; a smooth curve for the monohydric alcohols; a curve with a minimum point for the n -aldoximes and for the dialkylsulfones; and an altogether irregular curve for the amides of monobasic acids. Even allowing for errors in melting points of less easily accessible compounds, it is not evident that there is justification for choosing one homologous series from this group and basing on it an argument for the valence hypothesis. Thus the proposed explanation of the zigzag curve of the dibasic acids is misleading.

(c) Double bonds between carbon atoms are next taken up. Of the three possible formulas, \rightleftharpoons , \Rightarrow , and \Leftarrow , \rightleftharpoons is chosen as the stable arrangement from the fact that the stable hydrocarbon, propene, gives, on treatment with hydriodic acid, a mixture of primary and secondary propyl iodides. Since the iodine (negatively charged) goes partly to each carbon atom it is assumed that there must be positive ends of bonds on both carbon atoms, indicating the formula $\text{CH}_3\text{CH} \rightleftharpoons \text{CH}_2$. Since this reaction is offered as evidence for assuming a symmetrical distribution of the positive and negative charges between the two unsaturated carbon atoms, it is somewhat surprising on examining the quantitative data to discover that over 99.5% of the product of the reaction is the secondary propyl iodide. The authors tell us that this is due to the influence of the methyl group. The addition of ClBr and ClI to propene is somewhat better, the ratio of the two possible addition products being 7 : 5 and 4 : 1, respectively. These reactions furnish the entire basis for determining how the double bond is to be written in all stable compounds with the ethylene linkage. It is not evident to the author how the above facts furnish any reason for assuming any connection whatever between the direction of the valences and the course followed by such addition reactions.

Furthermore, the addition of halogen acids to alkenes is a still more perplexing matter than is here implied. The author has investigated extensively the addition of hydrobromic acid to isobutene, and has ob-

¹ Levene and Jacobs, *J. Biol. Chem.*, 18, 463 (1914) have recently published data for the m. ps. of the acids $\text{C}_{11}\text{--C}_{16}$ which assign to the acid C_{16} a higher value than that of C_{14} . The melting point curve for the series therefore loses its zigzag character at this point, but retains it elsewhere.

tained by this process products containing all the way from 0% to 55% of isobutyl bromide, the remainder being tertiary bromide, depending upon experimental conditions. A reaction which may be subject to such wide variation can be of little value as evidence for any valence hypothesis.

(d) The theory is applied to double bond isomerism of the maleic-fumaric type. The most obvious objection to this application, namely, that three isomers are in general predicted by the theory whereas in nearly all cases only two are known, is forestalled by the statement of the authors that the prediction of unknown facts by a theory is a far less serious fault than the failure to account for known ones, and the convenient assumption that all the predicted but unknown isomers are very unstable if not incapable of isolation. There must surely be limits beyond which this attitude becomes unsafe. But to the theory even with these elastic reservations, there are objections.

The case of the cinnamic acids, referred to by Nelson, Beans and Falk as one where the expected number of isomers exist, has now become rather an argument against their hypothesis, since the existence of four isomers has been established, the theory calling for three, while the recent work of Stobbe and Schönburg¹ has shown them not to be due to polymorphism, but, apparently, to chemical isomerism.

There is also further objection to the use of the theory for this type of isomerism. In the preceding argument, (c), the formula for propene is deduced from its behavior on addition of hydriodic acid, the assumption being made that the iodine tends to unite with such carbon atoms as carry the positive ends of valences, that is, positive charges. The isomeric unsaturated acids (maleic-fumaric type) are now assumed to differ in the directions of their valences, \rightleftharpoons , and \Rightarrow . If the argument applied to propene is of any significance, then the isomeric unsaturated acids must give different addition products with halogen acids. Unfortunately it is with the halogens that such so-called geometrical isomers give isomeric addition products (stereoisomeric products), whereas it is well known that with halogen acids the addition products are the same from both members of such a pair.² It is impossible to see the slightest ground for the use of these polar valences in connection with this type of isomerism.

(e) The existence of unexplained isomeric nitrotoluenes and other compounds described by Ostromisslensky³ is accounted for by isomerism of the above type in the benzene ring. In view of our slight knowledge as to the nature of such isomerism the case can hardly be discussed profitably. The Kekulé theory would explain it as satisfactorily.

¹ *Ann.*, **402**, 187 (1913).

³ *Z. physik. Chem.*, **57**, 341 (1907).

(f) When it comes to application of the conception to the behavior of compounds with the acetylene union, it will first be necessary to explain some of the inconsistencies noted under (d) and formulate a somewhat exact system of hypotheses before the discussion can be profitable.¹

The paper from which the above illustrations are taken takes up numerous other organic problems—the diazo compounds, tautomerism, etc., but little more is shown than that the formulas of the compounds could be written in this new nomenclature, the problems being complex ones and the theory elastic.

The further the electron conception of valence is developed the more qualifying factors we have to admit. In a later paper,² Falk presents a classification of the unsaturated acids, in the attempt to show that when the bonds of the unsaturated linkage are directed in certain ways the affinity constants of the acids fall within certain limits.

The value of the classification in itself or as evidence for the valence theory, however, becomes small when we note that outside of a rather restricted number of compounds the values of the affinity constants depart widely from those predicted. This is attributed to "constitutive influences." But if this new theory of chemical combination contributes nothing to the elucidation of this large unknown factor of organic chemistry, it becomes still more difficult to find proof for it in its application to the more complex problems.

Most applications of the electron theory of valence have been in connection with some of the most perplexing questions of organic chemistry. We are, however, not justified in applying a hypothesis merely because it provides a convenient method of formulating or even of correlating a limited number of phenomena, if it is inconsistent as soon as we step outside narrow limits, or if it is not fundamentally suited to explain the manner of chemical combination. The author has little sympathy with the statement of Falk³ that its "convenient symbolism alone... would justify its use in practical work." This conception of valence involves necessarily certain assumptions regarding the nature of union between atoms and the mechanism of chemical reactions, and there are certain questions to which I would call attention.

The statement is made by W. A. Noyes⁴ that "all reactions involving decomposition of molecules are preceded by an ionization of the parts of

¹ Only a slight examination of the somewhat confusing relations between the isomeric unsaturated acids and the corresponding saturated compounds is needed to show how superficial are the arguments put forward by Falk for the application of the electron conception of valence to the various types of unsaturated compounds.

² THIS JOURNAL, 33, 1140 (1911).

³ *Ibid.*, 35, 1811 (1913).

⁴ *Ibid.*, 23, 460 (1901). An interesting discussion of this question is to be found in the article by Berthoud, *J. chim. phys.*, 10, 578 (1912).

the molecule," and this view is evidently adopted by other advocates of this conception. Thermal dissociation of such molecules as hydrogen, hydrogen chloride, phosphorus pentachloride, etc., is thus assumed to yield primarily charged atoms or radicals. Let us examine the reaction between hydrogen and chlorine, as formulated by Fry.¹ The bracketed reaction appears to be implied and is added by the author. The decomposition of hydrogen chloride would, of course, involve the reversal of these steps.

The electromer $\overset{-}{\text{H}} - \overset{+}{\text{Cl}}$ must be present in traces only, since otherwise there is no reason why it should not ionize in solution, and why, for example, chlorine should not appear at the cathode in electrolysis. This electromer is thus very unstable.

Let us consider the following question: Why does HCl exist in preference to the system $\text{H}_2 + \text{Cl}_2$? Instead of saying that H and Cl atoms have a greater affinity for each other than for other atoms of their own sort, the electron conception of valence would enable us to be more specific and state that H and Cl have a great tendency, respectively, to lose and gain an electron. Here we are apparently nearly touching upon Abegg's "electroaffinity," although he assumed atoms to become charged only when ionization occurred.

One of the fundamental problems of chemistry is surely the determination or exact specification of the relative tendencies of various sorts of atoms to combine with each other, but it is not certain that we are greatly assisted by restating the problem as that of determining the relative tendencies of atoms to gain and lose electrons from each other. The somewhat puzzling stability of the hydrogen and chlorine molecules is not explained merely by writing signs above the atoms. Nor can we so easily escape the conflicts that arise in trying to assign relatively positive and negative characters to different elements. For example, if chlorine and hydrogen combine with each other for the reason suggested above, we must also expect that chlorine would combine with any element somewhat more or less negative than itself more energetically than with itself, but the properties of oxides of chlorine or of Br-Cl do not bear out this expectation.

If we look further into this question of the relative tendencies of differ-

¹ THIS JOURNAL, 23, 263 (1914).

ent atoms to gain and lose electrons, we have not to go far to find inconsistencies among the electronic formulas. For example, we find, according to Jones¹ that the compound $(\text{CH}_3^+)_3 \equiv \text{N} \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{Cl} \begin{smallmatrix} - \\ \vdots \end{smallmatrix}$ changes to $(\text{CH}_3^+)_3 \equiv \text{N} \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{Cl} \begin{smallmatrix} - \\ \vdots \end{smallmatrix} \text{OH}$, the chlorine taking two electrons from the nitrogen. The compound $(\text{Cl}_3^-) \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{P} \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{Cl} \begin{smallmatrix} - \\ \vdots \end{smallmatrix}$ exists in equilibrium with $(\text{Cl}_3^-) \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{P} \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{Cl} \begin{smallmatrix} - \\ \vdots \end{smallmatrix}$. The compound $(\text{CH}_3^+)_3 \equiv \text{N} \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{Br} \begin{smallmatrix} - \\ \vdots \end{smallmatrix}$, however, is assumed not to change to $(\text{CH}_3^+)_3 \equiv \text{N} \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{Br} \begin{smallmatrix} - \\ \vdots \end{smallmatrix}$. We must conclude, then, that bromine has less tendency than chlorine to take an electron from nitrogen, that it is less negative.² Similarly the compound $(\text{CH}_3^+)_3 \equiv \text{N} \begin{smallmatrix} + \\ \vdots \end{smallmatrix} \text{O} \begin{smallmatrix} - \\ \vdots \end{smallmatrix} \text{CH}_3$ is quite stable. OH has thus also less tendency than chlorine to take an electron from nitrogen, that is, like bromine, it is less "negative" than chlorine. This conclusion is, however, contradicted by the assumption made throughout this paper by Jones and in other articles dealing with this subject, that the stable form of hypochlorous acid is $\text{HO} \begin{smallmatrix} - \\ \vdots \end{smallmatrix} \text{Cl} \begin{smallmatrix} + \\ \vdots \end{smallmatrix}$, the OH having taking an electron from the chlorine. It is here assumed to be more "negative" than chlorine. I shall mention this compound again below.

A hypothesis which deals with the nature of the attractive force between atoms contains inevitably expressed or implied assumptions regarding chemical affinity. If our above assumptions in connection with the hydrogen chloride equilibrium are incorrect, *then there is plainly great need of some explicit statement as to what principles do control the gain and loss of electrons, and how this property is related to chemical affinity.* With the whole theory in its present vague state, a multitude of contradictory hypotheses can easily be hidden by the complex and elastic nomenclature.

Since the algebraic sum of the positive and negative charges in any chemical compound or system must, according to our fundamental conception, be zero, it naturally follows that we shall never be at a loss to properly arrange the charges so that any ions may interact, provided we assume the proper exchanges of electrons. The reaction, sodium plus chlorine, would be somewhat different from that examined above.³

Evidently we must assume that one chlorine takes an electron from each of the two sodium atoms; or we may assume that we have

¹ THIS JOURNAL, 36, 1268 (1914).

² There is opportunity for confusion of terms here. By a "negative" atom is meant one tending to become negatively charged, the customary usage. This will of course be one tending to gain an electron, *i. e.*, one which before it gains the electron is presumably as a whole, or at some point, strongly positive.

³ Other simple reactions are formulated by Fry, THIS JOURNAL, 36, 267 (1914).

In this reaction and that between hydrogen and chlorine two assumptions are involved which must constantly be employed in applying the electron conception of valence. First, we assume a great mobility on the part of the electrons—such, in fact, that the nonexistence of the hypothetical less stable electromers is not surprising. Secondly, we assume the existence, always, in equilibrium, of all the possible electromers.

Once, however, these assumptions are admitted, all plausibility disappears from those arguments commonly employed by the advocates of the theory, in which the charge on some atom in a compound is deduced from the charge judged to be present on it after the compound has been subjected to a reaction of some sort. For example, hypochlorous acid, supposed to be $\overset{-}{\text{HO}}-\overset{+}{\text{Cl}}$ is a substance commonly used for reference. If a compound, say RCl, reacts thus:

it is concluded that the chlorine, positive in $\overset{+}{\text{Cl}}-\overset{-}{\text{OH}}$, must also be positive in RCl, thus $\overset{-}{\text{R}}-\overset{+}{\text{Cl}}$.¹

In the first place we must inquire further into the reasons for supposing hypochlorous acid to be necessarily $\overset{+}{\text{Cl}}-\overset{-}{\text{OH}}$. Oxygen is not necessarily negative any more than is chlorine. In fact, from its position in the periodic system, which according to Falk² must furnish the basis for distribution of the charges in the simpler compounds, we should expect it to be less inclined to carry the negative charge than chlorine. Here, where it has already gained one electron from the hydrogen, its tendency to take another should be rather decreased than increased. Why, then, is not the stable form of hypochlorous acid $\overset{-}{\text{Cl}}-\overset{+}{\text{OH}}$ rather than $\overset{+}{\text{Cl}}-\overset{-}{\text{OH}}$? There hardly appears to be justification for the certainty with which fry states³ that "to admit the existence of hypochlorous acid is to admit the existence of positive chlorine." We must ask again what principle is supposed to controll this gain and loss of electrons.

But, assuming the formula $\overset{+}{\text{Cl}}-\overset{-}{\text{OH}}$ to be correct, we must note that the substances reacting in the above equation are really to be represented as

¹ This type of argument is commonly employed, for example in two articles by Fry, *THIS JOURNAL*, 36, 248 and 262 (1914); Nelson, Beans and Falk, *Ibid.*, 35, 1816 (1913) designate such hydrolytic reactions as one of the chief means for determining the charges present on atoms.

² *THIS JOURNAL*, 32, 1637 (1910).

³ *Ibid.*, 36, 267 (1914).

With this scheme as a basis there will be no difficulty in explaining the formation of compound (d) from compound (b), or of (c) from (a). Assuming the formula of HOCl to be known it is clear that we cannot draw conclusions as to the formula of our compound RCl. Further conclusions as to which of the ions present are reacting with each other will appear to depend upon assumptions, based on analogy, as to the relative affinity of various radicals for each other, just such as most organic chemists employ, expressed in some terms or other.

In view of these supplementary hypotheses which the electron conception of valence has come to demand, which permits us to distribute the electrons largely in accordance with the exigencies of the particular equation in hand it appears to the author to have developed into merely a new system of nomenclature, desirable, if correct, but as far without direct support. This complex array of hypothetical electromeric substances does not appear to be an acquisition to the science which is desirable in itself.

Of the other applications of the theory to more complex problems the author would mention only that of Fry³ to the question of substitution in the benzene ring. The rule governing the position of substituents which Fry puts forward with the utmost confidence⁴ is so simple as to arouse distrust at once. It would appear sufficient to say that in view of the extensive investigations carried on in this field in recent years by Hollemann, Flürscheim, Obermiller and others, if any such simple rule could cover the facts it would have been discovered long ago empirically, even if not expressed in the same terms. Hollemann⁵ has, however, recently called attention to a number of cases of substitution reactions where it is quite impossible to apply Fry's rule.

Bray and Branch,⁶ and Lewis⁷ have recently advocated the view that there are both "polar" and "nonpolar" bonds. Certain difficulties appear to lie in this hypothesis, one of them being that mentioned by Nelson and Falk⁸ of determining which bonds are polar and which not. Additional

¹ Jones, *THIS JOURNAL*, 36, 1277.

² *Ibid.*, 1282.

³ *THIS JOURNAL*, 36, 248 (1914).

⁴ *Ibid.*, p. 252.

⁵ *Ibid.*, 36, 2495.

⁶ *Ibid.*, 35, 1440 (1913).

⁷ *Ibid.*, 35, 1448.

⁸ *Ibid.*, 36, 209 (1914).

hypotheses will also be needed in explaining such a reaction as a double decomposition between a polar and a nonpolar compound.

Lewis¹ gives a list of the characteristics of compounds with polar and nonpolar bonds, from which it is clear that no sharp dividing line exists. It does not appear altogether clear just how we are to conceive of bonds representing a gradation between the polar and nonpolar condition, particularly as regards their behavior in chemical transformations.

The chief reason prompting Lewis to favor polar bonds appears to be the desire to represent certain compounds as having a very indefinite and mobile molecular structure. What value this conception may have in itself can hardly be clear until it is developed further, but the author questions whether, if adopted, it involves necessarily the assumption of polar bonds.

The recently expressed view of J. J. Thomson² also employs the conception that the exchange of an electron occurs between certain atoms in certain molecules, this phenomenon being designated as intramolecular ionization; but it is to be noted that in such cases it is not a step necessary to the union of the atoms but a phenomenon, so to speak, superimposed on that. Furthermore it is evidently considered to be the exceptional rather than the usual occurrence in the case of atomic unions. The union of atoms through electrical forces is satisfactorily accounted for without it.

Thomson's reason for assuming such intramolecular ionization lies in the attempt to account for the high dielectric constants of certain substances and the fact that these dielectric constants depart from the value predicted by the rule of Maxwell expressing a relation between dielectric constant and square of the refractive index. The high dielectric constants of the substances are accounted for by the high electric moments of the molecules, and these in turn are attributed to transfers of electrons within the molecule.

It does not appear certain, however, that the large electrical moments of some molecules could not be accounted for in some other way. We are here on rather speculative ground from the physical point of view; and in a field where many assumptions would be possible, in view of the complex system of electrical charges which the molecule, according to Thomson's conception, will represent, we can hardly look for conclusive evidence for the phenomenon of "intramolecular ionization." Thomson's basis for the classification of "polar" and "nonpolar" compounds is also such that, as with that of Lewis, a sharp dividing line between the two will not appear.

Nelson and Falk³ raise other objections to the conception of both

¹ *Loc. cit.*, p. 1450.

² *Phil. Mag.*, [6] 27, 757 (1914).

³ *THIS JOURNAL*, 36, 210 (1914).

polar and nonpolar bonds, and since one of these would be as well an objection to a theory involving no polar bonds I shall refer to it here. They note that this view would represent the gradual oxidation of methane to carbon dioxide as a series of steps without any change in the charges on the carbon atom, and they remark that such a supposition is untenable. This statement is somewhat too categorical in view of the fact that it is only the assumptions involved in the theory they are defending that render it untenable. If we choose to assume no charges on the carbon, the picture of the oxidation process is moderately satisfactory. It is the definition of oxidation put forward by the advocates of the electron theory, based on the behavior electrolytes in aqueous solution, which necessitates the assumption of the charges on the carbon.

There appears to be little justification for any very dogmatic statements regarding the oxidation of methane. The oxidation of Fe'' to Fe''' in aqueous solution is, for example, a process in which we suppose a change in the electric charge on the ions is concerned. But as far as the molecular forms of the reacting substances are concerned, we can only say that FeCl_2 is gradually replaced by FeCl_3 . It is quite an unproved assumption that the charges are still present on the iron in the undissociated molecules, except in as far as the advocates of this theory have proved it; it is then also an assumption that the change of FeCl_2 to FeCl_3 could not be brought about except by a process involving ionization and changes in which electric charges are concerned. It is thus also an assumption that anything ionic is involved in the replacement of the hydrogen of methane by oxygen. There appears to be in the paper of Falk and Nelson an underlying desire to consider all reactions ionic because some are. But it appears doubtful whether most, or even very many chemists are prepared to adopt this position. The tendency among organic chemists appears to be rather in the opposite direction, since the view long advocated by Michael that the first step in chemical reactions is the formation of a complex molecule by the reacting substances has recently been taken into consideration by numerous investigators, for example, Fischer,¹ Kauffmann,² Gadamer,³ Schmidlin,⁴ Baume,⁵ Berthoud,⁶ and others. Electrolytic dissociation is thus considered as a special phenomenon occurring with certain substances in certain solvents. Furthermore, the process of electrolytic dissociation, even when it occurs, is no longer regarded as necessarily the step through which the electrolyte reacts, as is evidenced by many recent investigations of Acree, Stieglitz, Bredig and others.

² *Die Valenzlehre*, p. 336 (1911).

³ *J. prakt. Chem.*, [2] 87, 312 (1913).

⁴ *Ber.*, 45, 899 (1912).

⁵ *J. chim. phys.*, 12, 206 (1914).

⁶ *Ibid.*, 10, 578 (1912).

The author finds another strong objection to the electron conception of valence, perhaps shared by others, in the assumption that all decompositions of molecules are processes of ionization. When one considers the very great difference between the equilibrium in the reaction $\text{HCl} \rightleftharpoons \text{H} + \text{Cl}$, under the influence of heat, and that in the reaction $\text{HCl} \rightleftharpoons \overset{+}{\text{H}} + \overset{-}{\text{Cl}}$ as it occurs in aqueous solution, it seems strange to assume that in both cases we have charged hydrogen and chlorine atoms moving about in the neighborhood of each other, under the influence of the same attractive force except for a certain difference in the dielectric constant of the medium.

For any direct evidence as to whether or not atoms of elementary substances are electrically charged during reaction, we must for the present turn to physical investigations of gases. Here, as pointed out by Bates,¹ such evidence as can be found is against the hypothesis. In addition to the opinion expressed by J. J. Thomson we would also note that Le Blanc and Volmer² have recently added to the evidence that in a reacting mixture of hydrogen and chlorine the atoms of these elements are not present in the charged conditions except when under specific ionizing influences.

In conclusion the author would again call attention to the fact that the "electron conception of valence" cannot avoid dealing with the question of chemical affinity, *i. e.*, the attractive force between atoms. It has already developed into a complex mass of hypotheses, both fundamental ones dealing with the existence of electromeric substances, etc., and supplementary ones regarding the electronic formulas of particular substances. Many statements made very categorically are really only hypothetical. It appears to the author quite unjustifiable to go further without explicit statements regarding such questions as the following:

Do atoms which have not gained or lost electrons attract each other? If so, by what means?

What is supposed to be the magnitude of this force existing before the exchange of electrons as compared with that after such an exchange?

What fundamental principle controls this tendency of atoms to gain and lose electrons? That is, what is the fundamental principle on which we are to determine the electronic formulas of substances?

What is the relation, if any, between this tendency and what we usually speak of as the affinity between various atoms?

It could well be said that such questions carry us too far into detail in a field where everything is speculation, if it were not for the fact that assumptions regarding them are involved in every application of the electron conception and that the lack of explicit hypotheses permits inconsistencies to remain concealed too easily. That the whole theory is

¹ *Loc. cit.*

² *Z. Elektrochem.*, 20, 494.

quite hypothetical is quite clear from the fact that there is not a single well established case of the existence of such electrical isomers as we are constantly being asked to assume in great numbers. We must at least ask that the hypotheses involved shall be made very explicit.

Summary.

In the above paper the following objections are raised to the electron conception of valence:

1. The chemical evidence advanced in support of this hypothesis, in as far as it deals with simple phenomena is quite unconvincing.
2. Any application of the theory involves the constant use of assumptions that render it too elastic to be proved or disproved by these applications.
3. The electromeric formulas assigned to chemical compounds are inconsistent with any rule that can be proposed.
4. No single well-established case of electroisomerism is yet known.
5. The evidence of physical experiments is at present opposed to the assumptions on which it is based.
6. The conception necessarily involves assumptions regarding the attractive force between atoms, the attraction of various atoms for electrons, and the relation of this last property to chemical affinity. A number of questions are proposed which should be answered—at least, the hypotheses to be adopted regarding them should be explicitly stated—before the theory is applied to the most perplexing problems of organic chemistry.

Received February 5, 1915.

Introduction.

If, in the formula for the diffusion coefficient, $dS = -Dq \, dc/dx \, dt$, we regard D as the quantity of the dissolved substance in grams or mols which in unit time, t , passes through the unit distance x in unit cross-section, q , with unit fall of concentration,— c , occurring in this distance, likewise expressed in grams or mols, and if we divide D by M , the molecular weight of the compound in question, then D/M ($= I$, the ideal diffusion coefficient) indicates the quantity of the substance which would pass under the above conditions, provided that each molecule while retaining

its size, configuration, and free-path velocity, had its molecular weight reduced to unity, and, therefore, its momentum reduced to a corresponding degree.¹ By dividing the diffusion coefficients, determined at 20° in aqueous solution for nonelectrolytes, by the respective values of M , and plotting $\log D/M$ against $\log M$, the points so obtained have been found to lie on a straight line not passing through the origin, and whose equation must be, $\log D/M + n \log M = \log K$, where n is the slope of the line, and K proves to have practically the same value for a great variety of substances. By taking the antilog of both sides, a new fundamental law of diffusion, $DM^{n-1} = K$, has been obtained, according to which we can write $M = (K/D)^{1/n-1}$, and determine M for nonelectrolytes for which D has been measured experimentally.²

With the available data concerning the diffusion of the metals in liquid mercury, it has been found possible by means of this law to study the constitution of certain dilute, liquid amalgams, and it has been shown that, at ordinary temperatures, the metals indicated exist in mercurial solution in molecular forms corresponding to the formulas: Zn, Cd, Sn, Pb, AuHg₂, TlHg₂, LiHg₃, NaHg₅, CaHg₅, KHg₆, RbHg₆, SrHg₆, CsHg₆, BaHg₆.³

It is the object of the present paper to show that an analogous method can be applied in the study of the question concerning the hydration of the ions, the ionic mobilities in this case being treated in the same manner as were the diffusion coefficients of the metals in the study of the constitution of the dilute liquid amalgams. Such a method in the case of the ionic mobilities is justified by the following considerations.

Since at each moment, during the passage of electricity through the solution of an electrolyte, the individual (univalent) ions are under the influence of equal forces, the velocities of the individual ions, both positive and negative, are proportional to their equivalent conductances (mobilities). Also, the magnitude of the impelling force, which results from the potential gradient, and which acts upon the ions, is, under like external conditions, equally great for all univalent ions.⁴ And, moreover, the conductance of a solution of a binary electrolyte, in which there is present a

¹ In the original paper (*THIS JOURNAL*, 36, p. 848, l. 38) the expression "to the reciprocal value" was used. The passage should read: "but the momentum of each such imaginary molecule of unit molecular weight would be equal only to $1/M$ times that of a molecule of the real compound." This correction should also be applied to the definition of the ideal diffusion coefficient given on p. 849, l. 10.

² G. McP. Smith, *THIS JOURNAL*, 36, 847 (1914).

³ G. McP. Smith, *Z. anorg. Chem.*, 88, 161 (1914); cf. also E. Beckmann and O. Liesche, *Ibid.*, 89, 171 (1914).

⁴ For ions of the valence n the impelling force is, of course, n times as great. But polyvalent ions, owing to their tendency to enter into the formation of intermediate ions and other complexes, which renders uncertain the extrapolated values obtained for their mobilities at infinite dilution, will not be considered in this paper.

given concentration of free univalent ions, is proportional to the sum of the mobilities of the latter; and, since the quantities of electricity transported by the anion and cation are directly proportional to their individual mobilities, it follows that the velocities of the individual ions, and therefore the numbers that pass in unit time through unit distance are proportional to their mobilities.

When an ion of the mass M is subjected to the action of a constant force, F , it receives a certain acceleration, a , such that we have the relationship expressed by the equation, $F = Ma$. At the same time, the ion is retarded in its motion by the resistance which it must overcome in its passage through the liquid. If the force continues to act, the ion finally acquires the limit velocity, c , that can be imparted to it by that force; and this velocity is independent of the mass of the ion, but depends upon the viscosity of the liquid and upon the size and configuration of the ion. After having acquired this limit velocity, the ion continues to move at a constant rate of speed, and the resistance R , which it then encounters is exactly equal to the force F , or, what is the same thing, the positive acceleration which the ion acquires from the force F is exactly equal to the negative acceleration which it receives from the resistance R . If, therefore, a given ion, while retaining its charge, size, and configuration, could have its mass, M , reduced to unity, the force F would still impart to it the limit velocity c , but its positive or negative acceleration would then be equal to $M \times a$.

If, now, the original ion of the mass M and the corresponding ideal ion of unit mass were both traveling at the limit velocity c , and the force F should suddenly cease to act, the resistance R would initially obtain in both cases; the ion of the mass M would meet with an initial negative acceleration equal to a , while the corresponding ideal ion of unit mass would encounter an initial negative acceleration equal to $M \times a$; or, the kinetic energy of the real ion would be equal to $\frac{1}{2}Mc^2$, while that of the imaginary ion would be equal to $\frac{1}{2}c^2$. That is to say, the periods of time, t , in which the forward progress of the two ions would be brought to a standstill, and the distances, s traversed by them, would bear to one another the approximate relationships:

$$t_1 : t_M = s_1 : s_M = \frac{1}{2}c^2 : \frac{1}{2}Mc^2 = c/M : c = l/M : l; \text{ and } s_1 = s_M/M.$$

Now, in the case of diffusion, according to the kinetic theory, the dissolved molecules (and what is said of the molecules applies equally well to the ions present in a salt solution) are incessantly moving about in irregular zig-zag paths, *with continually changing velocities*, and these are dependent not only upon the resistances encountered by the molecules, but also upon the masses of the latter; the mean free-path velocities of the molecules vary inversely as the square roots of their masses. There-

fore, if a molecule of the mass M has the free-path velocity c_M , and if, with its mass reduced to unity, it would have the free-path velocity c_1 , then, according to the kinetic theory, $c_1 = c_M \sqrt{M}$; the kinetic energies E of the respective molecules are $E_M = \frac{1}{2} M c_M^2$, and $E_1 = \frac{1}{2} c_1^2$, and these are equal. But if the corresponding ideal molecule, in addition to having its mass reduced to unity, be supposed also to retain its original free-path velocity c_M , then its kinetic energy $E'_1 = \frac{1}{2} c_M^2$, and this is equal, not to E_M , but to E_M/M . In that case, provided that the real and the ideal molecules make the same number of movements,¹ we should have for the two neutral molecules the relationships:

$$E'_1 : E_M = \frac{1}{2} c_M^2 : \frac{1}{2} M c_M^2 = c_M/M : c_M = s_M/M : s_M = D/M : D,$$

in which D is the diffusion coefficient of the compound in question; or, in the case of a similarly related pair of univalent ions, the relationships:

$$E'_1 : E_M = c_M/M : c_M = s_M/M : s_M = l/M : l,$$

in which l is the mobility of the ion in question.

The values of D/M are the ideal diffusion coefficients of the compounds, and those of l/M are proportional to the ideal diffusion coefficients of the ions in question. It should especially be noted that, in the foregoing discussion, ideal counterparts of the molecules of each separate compound (or ion) are imagined to exist, which, while retaining the exact size, configuration, and free-path velocity of the real molecules and ions, and while performing the same number of movements, differ from them only in that their masses are equal to unity.

Viewed in this light, the values of l/M assume a real physical significance, and we obtain in them a common denominator, to which the mobilities of the different ions might be reduced, if only their absolute hydration (*i. e.*, their ion-weights) were known. Since the l/M values are proportional to the ideal diffusion coefficients of the independent hydrated ions, we should expect in this case also to find the law to hold, that $lM^{n-1} = K$.

A. The Relative Hydration of the Ions.

During the last twenty-five or thirty years, there has been accumulated along various lines a great deal of evidence in favor of the view that the ions are more or less hydrated in aqueous solution.² Among the strongest

¹ After each movement, the ideal molecule is supposed to pause and wait until the real molecule has finished its movement, whereupon they both start out again together, and so on, over and over again.

Bousfield, "Ionengrößen in Beziehung zur Leitfähigkeit von Elektrolyten," *Ibid.*, 53, 257-313 (1905); E. H. Riesenfeld and B. Reinhold, "Berechnung der Ionenhydratation aus der Überföhrungszahl und der Beweglichkeit," *Ibid.*, 66, 672-86 (1909); and, especially, E. W. Washburn, "Hydrates in Solution: A Review of Recent Experimental and Theoretical Contributions," *Technology Quarterly*, 21, 360-449 (1908).

evidence in favor of this view is that which has been deduced from the results of transference experiments which have been carried out with various salt solutions in the presence of different nonelectrolytic reference substances. If at the end of such an experiment the ratio of water to nonelectrolyte has changed at the electrodes, then it follows either that the ions have carried water in the one direction, or that they have carried the nonelectrolyte in the opposite direction. Buchböck,¹ who was the first to obtain satisfactory quantitative results with this method, electrolyzed hydrogen chloride solutions, using mannite or resorcinol, at widely differing concentrations, as the reference substance; and, more recently, Washburn² has electrolyzed sodium chloride solutions with three different reference substances, sucrose, raffinose, and arsenious acid. These experiments all harmonize well together, and, unless we are prepared to assume that all of the different reference substances are capable of combining with the ions in the same way, the conclusion would seem to be justified that the changes in the ratio of water to nonelectrolyte at the electrodes are due, at least in the main, to the transfer of water from one part of the solution to another by the ions.

The relative degrees of hydration of chloride, hydrogen, potassium, sodium, and lithium ions, at 25°, in solutions containing about 1.25 formula weights of the metallic chlorides, and 0.1 formula weight of raffinose, to 1000 g. of water, or 1-1.5 formula weights of hydrogen chloride and up to 0.3 formula weight of mannite to 1000 g. of water, have been determined experimentally by E. W. Washburn,³ according to whom, if we assume that the hydrated chloride ion contains on the average 9 molecules of water, we have for these ions the degrees of hydration which are indicated in the first column of Table I.

² *THIS JOURNAL*, **31**, 322 (1909); *Z. physik. Chem.*, **66**, 513 (1909).

³ *Loc. cit.* The relative hydration of hydrogen and chloride ions are calculated by Washburn from a portion of the experimental data of Buchböck, who does not state the temperature at which he worked. Washburn, himself, did not work with hydrogen chloride solutions.

⁴ The mobilities given in the table are taken from a paper by A. A. Noyes and K. G. Falk, *THIS JOURNAL*, **34**, 479 (1912). The mobility of lithium ion at 25° has never been determined; the approximate value may, however, be calculated by means of the formula: l_0 25° = $K/M^{n-1} = 8888/(462.7)^{0.892} = 37.3$.

If, now, we plot the values of $\log l/M$ against those of $\log M$, we obtain the points shown in Fig. 1, which are seen to lie on the straight line AB . The slope of this line, n , is equal to $140 \div 74 = 1.892$.

Fig. 1.

On the basis of the assumption that 2 and 3 are the respective maximum coördination numbers of hydrogen and oxygen,¹ and that these ions there-

¹ The maximum coördination number of oxygen, according to Werner ("Neuere Anschauungen a. d. Gebiete d. anorgan. Chemie, ed. 1913, pp. 257-61) is 3, and from this it would seem to be likely that that of hydrogen is 2; upon this basis, assuming nonpolymerized water molecules, these hydrated ions correspond to the formulas,

dashes represent principal valences, and the dotted lines secondary valences. The polymerization of water can be interpreted as a necessary preliminary step in its ionization; e. g., $\text{HOH} + 5\text{H}_2\text{O} \rightleftharpoons [(\text{H}_2\text{O})_2\text{H}][\text{OH}(\text{H}_2\text{O})_3] \rightleftharpoons [(\text{H}_2\text{O})_2\text{H}]^+ + [\text{OH}(\text{H}_2\text{O})_3]^-$.

Interpolation compound.

fore contain at infinite dilution 2 and 3 molecules of water of hydration, the degrees of hydration of the other univalent ions whose mobilities have been determined can be calculated for infinite dilution at 18° , as follows:

For the line AB , in Fig. 1, we have the equation,

$$\log l/M + n \log M = \log K;$$

$$\text{whence,} \quad lM^{(n-1)} = K, \quad (1)$$

$$\text{and} \quad M = (K/l)^{1/n-1}. \quad (2)$$

Assuming that the same law holds at 18° for zero concentration, we have only to substitute in (1) the values of $l_{0, 18^\circ}$, and of M , for the two ions, and we get the relationships:

$$314.5 \times 37.04^{(n-1)} = K = 174 \times 71.05^{(n-1)};$$

$$\text{whence} \quad n = 1.9087,$$

$$\text{and} \quad K = 8378.$$

And, in order to calculate the hydrated-ion weights of the other univalent ions, we then substitute these values in (2):

$$M = (K/l)^{1/n-1} = (8378/l)^{1.1004}.$$

The values thus obtained, together with the numbers of hydrated water molecules, are given in Table II, and, in addition, the last column of the table contains the degrees of hydration calculated by Washburn from the experimental data at 25° , on the assumption that the chloride ion carries 9 molecules of water (cf. Table I).¹

It is very noteworthy that, starting with the data obtained at 25° by means of transference experiments with mixtures containing about 1.25 mols of electrolyte, 0.1 mol of reference substance, and 55.5 mols of water, assuming chloride ion to be combined with 9 molecules of water and taking the resulting experimental values for the other four ions, the law is found to hold, that $l_{0, 25^\circ} \times M^{n-1} = K$; and that, starting with the assumptions that hydrogen and hydroxide ions at infinite dilution, respectively, contain, at 18° , 2 and 3 hydrated molecules of water, and that the law, $l_{0, 18^\circ} \times M^{n-1} = K$, holds in this case, we obtain upon calculation practically identical values for the degrees of hydration of the same ions under these widely differing conditions. This fact furnishes confirmatory evidence that in each of the above mentioned transference experiments with electrolyte and nonelectrolytic reference substance, the changes in ratio between reference substance and water at the elec-

¹ In his paper, Washburn determines the relationship which exists between the degree of hydration of each of the four positive ions and that of chloride ion, and in a table he gives the number of molecules of water which are combined with each of these ions for different assumptions regarding the number combined with the chloride ion. In the present paper, those of Washburn's values are taken which are based upon the assumption that chloride ion is combined with 9 molecules of water; since in that case it results that 2 molecules of water are assigned to the hydrogen ion.

trodes were due almost wholly to the transfer of water, and not to that of reference substance, by the ions.

It should also be mentioned that Buchböck,³ who worked with solutions containing hydrogen chloride and reference substance at different concentrations, extrapolates his hydration values to zero concentration, both of hydrogen chloride and of the reference substance, and comes to the conclusion that, at infinite dilution, chloride ion is combined with 4 molecules of water for each water molecule that hydrogen ion is combined with; *i. e.*, if hydrogen ion carries 2 water molecules, chloride ion carries 8. This conclusion is in surprising agreement with the calculated value for chloride ion (Table II).

It is further interesting to note that Washburn and MacInnes⁴ have

¹ The mobilities given in the table, with the exception of that of hydroxide ion, are taken from the paper by Noyes and Falk, *Loc. cit.* The value for hydroxide ion is that given in Landolt-Börnstein-Meyerhoffer's Tabellen, 4th ed. (1912), p. 1124; it is less accurately known than the others, and may be 2 or 3% in error, while that for hydrogen ion is less than 1% in error (Private communication from Dr. S. J. Bates). Owing to the lesser accuracy of the determined values of l_0 18° for hydrogen and hydroxide ions, upon which the above table is based, it was not considered worth while in the case of the salts to use the somewhat more accurate values of Bates (THIS JOURNAL, 35, 519 (1913)).

² See below.

³ *Loc. cit.*

⁴ E. W. Washburn and D. A. MacInnes, THIS JOURNAL, 33, 1686 (1911).

drawn the conclusion from their cryoscopic data that, in 0.5 *N* solution potassium chloride is combined with about 9, and lithium chloride with about 18 mols of water more than caesium nitrate is combined with. By means of the data in Table II, we arrive at relationships for 18° and zero concentration which are in as good agreement with these conclusions as could be expected; the figures so obtained are that potassium chloride is combined with 6.6, and lithium chloride with 21.0 mols of water more than caesium nitrate is combined with.¹

In this connection, however, attention should be called to the fact that, by means of transference experiments, at 25°, with caesium chloride solution, with raffinose as the reference substance, E. B. Millard² has recently determined the relative degree of hydration of caesium ion; he concludes from his work that caesium ion carries 0.65 mol of water less than potassium ion does. According to him, if potassium ion combines with 10.5 mols of water, then caesium ion, under the same conditions, combines with 9.9 mols of water. This result is very surprising, when it is viewed in the light of the good agreement obtained in all other cases. Furthermore, additional evidence in favor of the calculated values is furnished in the next section, where it is shown that these values may be used to advantage in connection with the ideal diffusion coefficient and the hydrodiffusion of electrolytes.

B. The Ideal Diffusion Coefficient and the Hydrodiffusion of Electrolytes.

L. W. Öholm³ has determined, at 18° and 0.01 *N* concentration, the diffusion coefficients of the following highly dissociated electrolytes: NaCl, KCl, LiCl, KI, HCl, KOH, and NaOH. At infinite dilution—and the same would hold approximately at 0.01 *N* concentration—the ions of these electrolytes would diffuse independently, if it were not for their electrical charges; but the differences in potential, which result from the tendency of the lighter to precede the heavier ions, tend to hold the faster lighter ones back, while pulling the slower heavier ones forward. The net result, of course, is that the electrolytes diffuse upwards as a whole, virtually in the form of vibrating labile systems, each of which consists of one positive and one negative ion. Therefore, by taking as the molecular weights of the electrolytes the sums of the hydrated-ion weights of their positive and negative ions (Table II), it should be possible to successfully apply the conception of the ideal diffusion coefficient to the question of

¹ Washburn and MacInnes assume in their paper that caesium nitrate is not at all hydrated.

² Thesis submitted to the Graduate Faculty of the University of Illinois in partial fulfillment of the requirements for the Degree of Doctor of Philosophy in Chemistry, 1914, p. 28.

³ *Z. physik. Chem.*, 50, 309 (1904-05).

the hydrodiffusion of these substances. The data listed in Table III, in which the D_{18° values are those determined experimentally at 0.01 N concentration, show in a convincing manner that this actually can be done.

TABLE III.

Upon plotting the values of $\log D/M$ against those of $\log M$, the points shown in Fig. 2 are determined, and these are seen to lie upon the straight line AB , whose slope, n is equal to $140 \div 75 = 1.8667$. That is, upon taking into consideration the hydration of the ions, the diffusion of the highly dissociated electrolytes is found to be essentially no more com-

Fig. 2.

plicated than that of the nonelectrolytes; we have in this case also the law, $DM^{n-1} = K$. The values of K , which have been calculated for the different substances, are included in the last column of Table III. Their excellent agreement furnishes evidence which points almost convincingly to the correctness of the data calculated for ionic hydration at infinite dilution.

It will perhaps not be out of place also to note at this point that, by combining the two laws, $DM^{n-1} = K$, and $lM^{n-1} = K$, a diffusion formula can be obtained, which bears a striking resemblance to that developed along entirely different lines by Nernst.

For the diffusion of the hydrated electrolytes, we have

$$D_{18^\circ} M^{0.8667} = 270,$$

or, since $M_{\text{Electrolyte}} = M_{\text{Cation}} + M_{\text{Anion}}$, we have,

$$D_{18^\circ} = 270 / (M_K + M_A)^{0.8667}. \quad (3)$$

In the case of the hydrated ions, we have,

$$M_K = (K/l_K)^{1/n-1} \quad \text{and} \quad M_A = (K/l_A)^{1/n-1};$$

or,

$$M_K = (8378/l_K)^{1.1004} \quad \text{and} \quad M_A = (8378/l_A)^{1.1004}.$$

Substituting in (3) these values of M_K and M_A , we obtain,

$$D_{18^\circ} = \frac{270}{[(8378/l_K)^{1.1004} + (8378/l_A)^{1.1004}]^{0.8667}} = 0.04896 \left(\frac{l_K^{1.1004} \cdot l_A^{1.1004}}{l_K^{1.1004} + l_A^{1.1004}} \right)^{0.8667}. \quad (4)$$

According to Nernst,¹ on the other hand, $D_{18^\circ} = 0.04485 \left(\frac{l_K \cdot l_A}{l_K + l_A} \right)$

This formula furnishes values for infinite dilution.

By means of the formula, $D = K/M^{n-1} = 270 / (M_K + M_A)^{0.867}$, it is of course possible to calculate the diffusion coefficients of other uni-univalent electrolytes, for 18° , at 0.01 *N* concentration. For nitric acid and sodium iodide, for example, we obtain the values 2.18 (2.13, at 0.13 *N*) and 1.17 (1.115, at 0.086 *N*).²

In conclusion, a summarized list of the cases in which the law, $DM^{n-1} = K$, has been found to hold, together with the corresponding values of n and K , is given in Table IV:

¹ Theoretische Chemie, 5th ed. (1907), p. 371, Equation 8. For the diffusion coefficients of hydrogen chloride and sodium hydroxide, we obtain by means of Nernst's formula the values, 2.431 and 1.558; the writer's Formula 4, gives 2.294 and 1.505; Öholm's values are 2.324 and 1.432.

² The values in parenthesis are given by Öholm (*Loc. cit.*, p. 333), who obtains them by recalculation to 18° of Scheffer's value for nitric acid, and of Kawalki's value for sodium iodide.

URBANA, ILL.

[COMMUNICATION FROM THE CHEMICAL LABORATORY OF PRESIDENCY COLLEGE.]

THE INFLUENCE OF AN ALTERNATING CURRENT ON ELECTROLYSIS BY A DIRECT CURRENT.

[PART II.]

BY JNANENDRA CHANDRA GHOSH.

Received January 26, 1915.

In a previous communication² the action of an alternating current of high frequency on simple voltaic cells was studied. In this communication the influence of an alternating current on electrolytic cells will be described.

Löb³ investigated the solution of metals in potassium cyanide solution under the influence of unsymmetrical alternating currents. Von Wartenburg and Archibald⁴ investigated the formation of ozone at the anode in sulfuric acid solution by means of an alternating current impressed on a direct current. The object of this investigation, however, is to determine how an alternating current affects the phenomenon of electrolysis in general.

The poles of a four-volt lead accumulator were connected through the secondary circuit of an induction coil, and a suitable resistance, to the two electrodes of a voltameter. The induction coil used was a small one,

¹ In the former paper, the values given for this case are erroneous. Only a portion of Öholm's data was available at that time, and upon taking into consideration also his later work at 10°, the values given in this table are found to be correct (cf. L. W. Öholm, *Z. physik. Chem.*, **70**, 393ff. (1910); *Medd. k. Vetenskapskad. Nobelinstit.*, Vol. 2, No. 23 (1913)).

² THIS JOURNAL, **36**, 2333 (1914).

³ *Z. Elektrochem.*, **12**, 79 (1906).

⁴ *Ibid.*, **17**, 812 (1911).

as is generally used in the measurement of conductivity by the Kohlrausch method, and had a frequency of about thirty thousand per min. The amount of electrolytic decomposition in a given amount of time was estimated—firstly when there was an alternating current in the circuit and secondly, when there was no such current.

Electrolysis in Reversible Cells.—The silver voltameter was the first cell to be studied. Care was always taken that the voltameter in the two cases should be identical; otherwise, there is the possibility of the resistance of the circuit being different in the two cases, thus vitiating the accuracy of the results. This was secured by using the same platinum crucible, by filling it up with the silver nitrate solution to the same height, and by using identical silver anodes.

No. 1. (a) Weight of silver when there were both the direct and the alternating current in the circuit, 0.2451 g. in two hours.

(b) Weight of silver when the direct current was flowing through the above circuit for two hours, 0.2415 g.

No. 2. (a) Weight of silver, 0.2873 g.

(b) Weight of silver, 0.2904 g.

It will be seen that there is practically no difference in the amount of electrolytic decomposition in the two cases. We have already seen that, when an alternating current is passed through a reversible voltaic cell, there is no change in the electrode potentials of the cell. A reversible electrolytic cell remains likewise unaffected by an alternating current.

Electrolysis in Irreversible Cells.—In this type of cells it is rather difficult to get correct results. The back electromotive force of polarization becomes constant when the current has passed through the circuit for a considerable time; furthermore, the gases evolved are somewhat soluble in water. These sources of error could be partially eliminated by making the measurements after the current has already passed through the circuit quite a long while. In all the experiments the source of the current was a four-volt battery of two lead accumulators and the current passing through the primary of the induction coil was 0.33 ampere. The external metallic resistance was always kept constant. The results obtained are given in the following tables.

It will be seen that in most of the cases studied, a greater amount of current flows through the circuit during the passage of an alternating current. The exceptions are No. 4 in Table I, No. 5 in Table II, and No. 5 in Table IV. In these exceptional cases the cathodes used were of Pt black, copper or iron. It will also be observed that the smaller the area of the electrodes, the greater is the actual difference between the amount of current in the two cases. In the electrolysis of acids the alternating current is specially efficacious in the case of the cell where mercury is the cathode.

Alternating Current of Itself Ineffective to Bring about Visible Decomposition.

It might be supposed that the alternating current of itself forms the electrolytic gas, as had been observed by Van Name and Grafenberg¹ who used an alternating current having a frequency of 6600 per minute. Experiments were therefore performed to determine whether an alternating current from a small induction coil having a frequency of 30000 per minute could produce any perceptible amount of gas. The results obtained were always in the negative. This result is quite in accord with the observation of LeBlanc² that the action of alternating current diminishes regularly as the number of alternations per minute increases. Besides the strength of the alternating current is too small. The increase in the amount of electrolysis, when there is an alternating current in the circuit, is therefore not due to the electrolysis caused by the alternating current of itself.

¹ *Z. Elektrochem.*, 10, 303^r (1904).

² *Ibid.*, 11, 705 (1905).

The only assumption that could reasonably be made as to the cause of this great increase in the amount of current, when an alternating current plays in the circuit, was that the alternating current in some way decreased the back electromotive force set up in the cell. We may refer in this connection to the work of K. Bennewitz¹ who noticed that when electromagnetic waves were allowed to pass through an electrolytic cell, the decomposition potential sank to 1.24, the theoretical value for the oxy-hydrogen cell.

Experimental Method.—The experiment to determine how the discharge potentials of ions are affected by an alternating current, was arranged in the following way:

A is a battery from which a current of variable voltage passed through the electrolytic cell C. Between the battery and the cell are interposed a milliammeter and the secondary of the induction coil. An alternating current is developed in the secondary by passing a current of 0.33 ampere through the primary and the milliammeter is read when the current

FIG. 1.

passing through the circuit has become constant. In this connection, it may be remarked that the milliammeter remains absolutely steady during the passage of the alternating current. That the milliammeter also records the exact current strength during the passage of the alternating

¹ *Z. physik. Chem.*, 72, 223 (1910)

current was tested by interposing a silver voltameter in the circuit and comparing the readings of the ammeter with the weight of silver obtained. The E. M. F. at each electrode of the electrolytic cell against a decinormal calomel electrode is then measured by means of the potentiometer. The alternating current is now stopped, the milliammeter again read, and the new electrode potentials of the electrolytic cell measured.

The diminution in discharge potential completely accounts for the increase in current strength on the passage of the alternating current. The results obtained with some of the typical electrolytes are given in the following tables. The remarkable drop in the value of the discharge potential will be at once evident. Now, the strength of the current $C = (E - E')/R$, where E is the voltage of the electrolytic current, E' the back electromotive force of polarization. It was always found, that the diminution in the value of E' on the passage of the alternating current completely accounted for the increase in current strength.

TABLE V.

Electrodes of Pt 8.5 sq. cm., each dipped in 0.5 M H_2SO_4 .

	Strength of current. Amp.		E. P. at cathode. Volt.		E. P. at anode. Volts.

2.....	0.0228	0.0300	-0.850	-0.590	+1.630	+1.590
3.....	0.0160	0.0230	-0.810	-0.550	+1.620	+1.590
4.....	0.0060	0.0121	-0.770	-0.520	+1.550	+1.550
5.....	0.0028	0.0040	-0.505	-0.500	+1.490	+1.480

The E. P. of the calomel electrode is taken as zero.

The current strength is altered by varying the voltage of the electrolytic current. The current potential curve is given in Fig. 2.

The electrode potentials at the cathode appear very great but they are in fair accord with those obtained by Newbury¹ with his commutator short-circuited. The diminution in the cathode discharge potential when the alternating current passes through the circuit simultaneously with the direct current, is far greater than the diminution in the anode discharge potential. The effect of decreasing the size of the electrodes could be easily seen by comparing the values recorded in Tables V and VI.

¹ *J. Chem. Soc.*, 14, 19 (1914).

In Expt. 1, Table VI, the cathode discharge potential falls from 0.91 to 0.63 whereas in Expt. 1, Table V, the cathode discharge potential diminishes from 0.82 to 0.66 volt. The anode potential is also much more affected when the area of the electrodes is made smaller. In the current potential curves it will be noticed that in the case where simply a direct current

FIG. 2.

passes there is a sharp break at about 2.30 volt. This break is entirely absent when the alternating current passes simultaneously with the direct current. There is also another break in the current potential curve at about 1.95 volt. This latter break, however, occurs at a slightly lower potential when there is a simultaneous alternate current in the circuit.

Now these breaks are attributed by Nernst,¹ Glaser,² Bose,³ to be due to a new variety of ions getting discharged at these points. It therefore follows that whenever such a break disappears on the passage of an alternating current, the liberation of these new ions has been somehow prevented.

The next cells to be studied had mercury as the cathode.

TABLE VII.

Hg as cathode (3 sq. cm.) and Pt as anode (8.5 sq. cm.), electrolyte 0.5 *M* H₂SO₄.

	Strength of current. Amp.		E. P. at cathode. Volts.		E. P. at anode. Volts.	
	DC.	DC + AC.	DC.	DC + AC.	DC.	DC + AC.
1.....	0.0210	0.0300	-1.535	-1.140	+1.600	+1.640
2.....	0.0095	0.0180	-1.490	-1.040	+1.540	+1.63
3.....	0.0040	0.0120	-1.360	-0.980	+1.400	+1.530
4.....	0.0010	0.0050	-1.110	-0.820	+1.370	+1.500
5.....	0.0005	0.0025	-0.820	-0.660	+1.360	+1.480

The effect of the alternating current in this cell is very great. The alternating current affects chiefly the cathode when there is a large drop in potential. It will be noticed that the anode potential increases during the passage of the alternating current. This is due to the greater amount of current passing through the circuit in consequence of the large drop in potential at the cathode, and the inability of the alternating current to exert its depolarizing action on the anode. It will also be noticed that the increase in the anode discharge potential becomes very prominent at the back E. M. F. values lower than 2.65 volt, where there is a break in the current potential curve. This value is in agreement with the data given by Caspari⁴ for the E. M. F. required to produce visible decomposition. It is, however, very peculiar that this break disappears when an alternating current passes simultaneously with the direct current through the circuit. In this case, the break appears at a much lower voltage, about 2.2 volt. The current potential curve is given in Fig. 3.

³ *Ibid.*, 5, 153 (1868).

⁴ *Z. physik. Chem.*, 30, 89-97 (1899).

It was thought interesting to determine whether by substituting a large foil of Pt black for the platinum anode of the previous cell, the increase in the anode discharge potential observed, during the passage of the alter-

FIG. 3.

nating current, could be eliminated. The results as recorded in Table VIII show, that the increase in potential, even in this case is quite large.

Here too it will be noticed that a break in the current potential curve

occurs at about 2.4 volt. This break disappears on the passage of the alternating current and a break at a much lower voltage occurs instead.

If the sulfuric acid solution in the above cell be substituted by any other acid solution, fairly analogous results are generally obtained. In Tables IX and X are given results obtained with oxalic acid.

TABLE IX.

Pt electrodes (area 8.5 sq. cm.) dipped in 0.1 *N* oxalic acid.

	Strength of current. Amp.		E. P. at cathode. Volts.		E. P. at anode. Volts.	
	DC.	DC+AC	DC.	DC+AC.	DC.	DC+AC.
1.....	0.0275	0.0320	-1.157	-1.000	+1.700	+1.670
2.....	0.0195	0.0222	-1.010	-0.910	+1.590	+1.590
3.....	0.0145	0.0170	-0.965	-0.850	+1.550	+1.550
4.....	0.0121	0.0150	-0.930	-0.820	+1.520	+1.520
5.....	0.0090	0.0110	-0.890	-0.770	+1.350	+1.405
6.....	0.0065	0.0080	-0.830	-0.720	+1.210	+1.275
7.....	0.0055	0.0070	-0.818	-0.700	+0.940	+0.995
8.....	0.0030	0.0045	-0.760	-0.650	+ .770	+0.815
9.....	0.0020	0.0030	-0.690	-0.600	+0.675	+0.720

Breaks in the direct current potential curves occur at about 2.65 and at about 2.2. The first break disappears on the passage of the alternating current. The break at 2.2 was noticed by Bose¹ and was supposed to be due to the discharge of COOH' ions. Below the voltage indicated by the second break, the anode potential increases markedly during the passage of the alternating current.

TABLE X.

Hg cathode (3 sq. cm.) and Pt anode (5 sq. cm.) electrolyte 0.1 *N* oxalic acid.

	Strength of current. Amp.		E. P. at cathode. Volts.		E. P. at anode. Volts.	
	DC.	DC+AC.	DC.	DC+AC.	DC.	DC+AC.
1.....	0.0168	0.0028	-1.615	-1.274	+1.750	+1.830
2.....	0.0092	0.0160	-1.520	-1.106	+1.510	+1.680
3.....	0.0068	0.0130	-1.470	-1.040	+1.480	+1.640
4.....	0.0045	0.0100	-1.430	-0.940	+1.400	+1.590
5.....	0.0032	0.0078	-1.385	-0.850	+1.210	+1.480
6.....	0.0018	0.0060	-1.310	-0.780	+1.000	+1.310

The results are quite analogous to those recorded in Table VII.

The behavior of the normal salts are quite different from that of the acids. The diminution in the cathode discharge potential, on the passage of an alternating current, which is so marked in the case of acids, is not so very prominent here, unless the size of the electrodes be made very small. The results are recorded in Tables XI, XII, XIII, XIV and XV.

¹ *Loc. cit.*

7.....	0.0016	0.0016	-0.900	-1.020	+1.435	+1.330

The alternating current decreases the discharge potential both at the cathode and at the anode, the effect on the cathode is more prominent. Experiments No. 6 and 7 in Table XII are peculiar in so far as the cathode discharge potential increases by the action of the alternating current. There is a break in the current potential curve at about 3.2 which disappears on the passage of the alternating current.

By substituting Pt black for the Pt anode, the effect of the alternating current becomes perceptibly less, as is shown in Table XIII, while if Pt black is used as cathode the influence of the alternating current becomes almost negligible.

7.....	0.0062	0.0080	-1.535	-1.440	+0.780	+0.785
8.....	0.0040	0.0060	-1.465	-1.380	+0.750	+0.750
9.....	0.0025	0.0033	-1.375	-1.340	+0.700	+0.710

By substituting Pt black for the Pt anode, there is not much change of the alternating current. Also the influence of the alternating current on electrolysis becomes perceptibly smaller. If, however, Pt black be used as cathode, the change in the discharge potential values on the passage of the alternating current becomes almost negligible.

The behavior of an oxidizing salt like potassium nitrate affords many points of interest. The results are recorded in Tables XVI, XVII, XVIII, XIX.

TABLE XVI.

The peculiarity with potassium nitrate solution is that the anode discharge potential always diminishes on the passage of the alternating current, while the cathode discharge potential increases under conditions of very low current density. The results of Table XVI appear magnified, as it were, in Table XVII, where the area of the electrodes is much smaller. But the break in the direct current potential curves occurs in both cases at about 3 volts. This break, however, is not noticeable when the alternating current passes through the circuit simultaneously with the direct current. We have seen before that the break at 3.0 volts in the current potential curve when the electrolyte is sodium sulfate disappears on the passage of the alternating current. These breaks at such high potentials probably indicate the discharge of the ions of the alkali metals. This discharge perhaps does not take place when the alternating current passes.

8.....	0.0030	0.0050	-1.510	-1.020	+0.740	+1.120

We have seen that by using a Pt black cathode, in the case of the electrolytes studied previously, the effect of the alternating current on electrolysis becomes negligible. But with potassium nitrate solution, such is not the case as is shown by the data in Table XVIII. The influence of alternating current is much greater when Pt black is the anode than when it is the cathode. In the former case, the anodic discharge potential increases on the passage of the alternating current, while the cathodic discharge potential decreases. There is a break in the current

potential curve at about 2.8 and it is at voltages below this break that the increase in the anode discharge potential on the passage of the alternating current becomes prominent. When Pt black is the cathode, the anode discharge potential diminishes, and the cathode discharge potential increases on the passage of the alternating current. Here too the increase in the cathode potential becomes much pronounced at voltages below the break which is noticed at about 2.55 volt.

TABLE XX.

The electrolytic cell consists of electrodes of Pt 2 sq. cm. each in a normal solution of NaOH.

	Strength of current. Amp.		E. P. at cathode. Volts.		E. P. at anode. Volts.	
	DC.	DC+AC	DC.	DC+AC.	DC.	DC+AC.
1.....	0.0270	0.0345	-1.940	-1.620	+1.030	+0.980
2.....	0.0125	0.0195	-1.840	-1.570	+0.990	+0.930
3.....	0.0075	0.0135	-1.790	-1.570	+0.970	+0.910
4.....	0.0030	0.0060	-1.500	-1.760	+0.930	+0.860
5.....	0.0020	0.0020	-1.200	-1.300	+0.900	+0.800

At first the discharge potential at both the electrodes diminishes on the passage of the alternating current. But under conditions of very low current density the cathode discharge potential increases on the passage of an alternating current. The peculiar point was always noticed, that when the strength of the direct current passing through the circuit, was very small, the alternating current produced no change in the magnitude of the direct current. The diminution in the value of the discharge potential at one of the electrodes, was counterbalanced by its increase at the other electrode. This phenomenon occurs at only voltages below that corresponding to a break in the current potential curve. The effect of an alternating current on the electrolysis of solutions of a large number of electrolytes was studied in the elaborate manner indicated before, and the results obtained with some of the typical ones only have been given. Table XXI, however, which gives an account of the results obtained, when the source of the electrolytic current has a definite potential, *viz.*, 4 volt, show to what extent the various electrolytes agree in their behavior.

In the case of the oxidizing and the reducing salts the diminution in the anode potential on the passage of the alternating is always very prominent. In the case of the other salts such as sulfates and carbonates the effect of the alternating current is not so marked on the anodic discharge potential. Of course this relation holds good only when electrodes of platinum are used; if, however, a large foil of Pt black is used as one of the electrodes an alternating current does not much affect the discharge potential on its surface.

Influence of the Density of the Alternating Current.—It has been observed before, how the diminution in the discharge potentials depends on the density of the alternating current; for the purpose of determining this factor, the area of the electrodes was varied, and an alternating current of almost constant value was sent through the circuit. This method has the disadvantage that the discharge potential, due to the direct current, increases when the electrodes were made smaller. To eliminate this difficulty, the surface of the electrodes was kept constant in area, but the external metallic resistance was varied. Care was taken that the current strength through the primary of the induction coil remained constant throughout. The results obtained are given in Tables XXII, XXIII, and XXIV. It will be at once evident from these tables that the greater the resistance of the circuit, the less is the effect of the alternating current on the discharge potentials at the electrodes.

An Alternating Current Exerts Its Action on the Surface of the Electrodes Only.—It has been observed above to be a general phenomenon that when an alternating current is impressed along with a direct current to an electrolytic cell the discharge potential at the surface of the electrodes is a good deal diminished. The question however, arises whether the sinuoidal current thus produced by the conjugation of the direct with the alternate current has the property of keeping the discharge

potentials at a low value, analogous to that possessed by an intermittent current, or whether the alternating current exerts any specific action on the electrodes quite independent of the direct current. In order to settle this point it is necessary to isolate the alternating current from the direct current, to arrange the experiments in such a manner, that the alternating current should act on the surface of the electrodes only, but should on no account pass through the whole circuit. For the purpose the electrolytic cell was thus modified.

Each electrode was made of two metal foils dipped in the electrolyte very close to one another and connected through a key and a suitable resistance to the terminals of the secondary coil. The resistance of the main circuit was so adjusted that when the auxiliary electrodes were connected to the primary electrodes, no increase in the value of the direct current was observed. The resistance of the electrolyte between a primary and an auxiliary electrode was so small, that almost the entire alternating current passed through them. The advantage of this ar-

FIG. 4.

rangement lies in the fact, that the alternating current acts independently of the direct current, and that the effect of the alternating current on each of the electrodes could be studied separately.

TABLE XXV.

Two anodes of Pt (1 sq. cm.), two cathodes of Pt (3 sq. cm.), the electrolyte 0.5 *N* H₂SO₄. Alternating current only passed through the anodes.

	Strength of current. Amp.		E. P. at cathode. Volt.		E. P. at anode. Volts.	
	DC.	DC+AC.	DC.	DC+AC.	DC.	DC+AC.
1.....	0.0270	0.0295	-0.910	-0.940	+1.730	+1.580
2.....	0.0215	0.0232	-0.840	-0.870	+1.680	+1.580
3.....	0.0170	0.0190	-0.840	-0.855	+1.670	+1.570
4.....	0.0127	0.0147	-0.830	-0.850	+1.660	+1.550
5.....	0.0064	0.0077	-0.830	-0.880	+1.620	+1.500
6.....	0.0040	0.0052	-0.800	-0.840	+1.600	+1.490
7.....	0.0014	0.0018	-0.750	-0.820	+1.550	+1.440

The effect of passing the alternate current through the anodes is to diminish markedly the discharge potential at that electrode. There is a simultaneous increase in the cathode discharge potential. This increase is to be attributed to the greater amount of current passing through the circuit. During conditions of very low current density the decrease in potential at the anode due to the alternating current is almost counter-balanced by a simultaneous increase at the kathode.

TABLE XXVI.

Two cathodes (1 sq. cm.) and two anodes (3 sq. cm.) in 0.5 *N* H₂SO₄. The alternating current only plays between the cathodes.

	Strength of current. Amp.		E. P. at cathode. Volts.		E. P. at anode. Volts.	
	DC.	DC+AC.	DC.	DC+AC.	DC.	DC+AC.
1.....	0.0254	0.0325	-1.050	-0.650	+1.660	+1.660
2.....	0.0178	0.0250	-1.040	-0.620	+1.650	+1.670
3.....	0.0135	0.0225	-1.020	-0.500	+1.630	+1.660
4.....	0.0100	0.0185	-0.980	-0.470	+1.610	+1.640
5.....	0.0060	0.0135	-0.890	-0.450	+1.590	+1.630
6.....	0.0036	0.0095	-0.800	-0.420	+1.560	+1.610
7.....	0.0012	0.0060	-0.750	-0.390	+1.520	+1.600
8.....	0.0010	0.0040	-0.570	-0.370	+1.500	+1.580
9.....	0.0009	0.0013	-0.340	-0.280	+1.470	+1.510

The effect of the alternating current is far more marked at the cathode than at the anode. The cathode discharge potential diminishes very considerably while the anode discharge potential increases, during the play of the alternating current between the cathodes.

TABLE XXVII.

Two cathodes of Pt (1.25 sq. cm.) two anodes of Pt (1.5 sq. cm.) 0.5 *M* H₂SO₄. The alternating current passes through the cathodes as well as the anodes.

	Strength of current. Amp.		E. P. at cathode. Volts.		E. P. at anode. Volts.	
	DC.	DC+AC.	DC.	DC+AC.	DC.	DC+AC.
1.....	0.0205	0.0332	-1.140	-0.600	+1.650	+1.500
2.....	0.0140	0.0240	-1.020	-0.580	+1.630	+1.500
3.....	0.0108	0.0198	-0.940	-0.560	+1.600	+1.490
4.....	0.0065	0.0158	-0.930	-0.520	+1.590	+1.490
5.....	0.0038	0.0110	-0.830	-0.490	+1.570	+1.490
6.....	0.0022	0.0072	-0.820	-0.470	+1.550	+1.490
7.....	0.0010	0.0045	-0.630	-0.420	+1.520	+1.480
8.....	0.0008	0.0020	-0.450	-0.390	+1.460	+1.450

Some peculiar points could be noticed in Table XXVII. The anode potential diminishes, on the passage of an alternating current only down to a definite value, *viz.*, 1.49 volt. The cathode discharge potential diminishes continuously and the diminution is much larger in amount.

TABLE XXVIII.

Two cathodes of Hg (0.75 sq. cm.), two anodes of Pt (2 sq. cm.) in 0.5 *M* H₂SO₄. The alternating current only passes through the cathodes.

	Strength of current. Amp.		E. P. at cathode. Volts.		E. P. at anode. Volts.	
	DC.	DC+AC.	DC.	DC+AC.	DC.	DC+AC.
1.....	0.0110	0.0210	-1.560	-1.020	+1.770	+1.820
2.....	0.0045	0.0130	-1.400	-0.870	+1.710	+1.740
3.....	0.0022	0.0082	-1.230	-0.700	+1.610	+1.680

The results obtained are quite analogous to those recorded in Table VII, where the alternating current passes along with the direct current in a cell having mercury as cathode and Pt as anode.

In Tables XXIX and XXX, in the experiments marked (a) only the direct current passes; in those marked (b), an alternating current plays between the cathodes; in those marked (c) the alternating current passes through the anodes only and in (d) through both.

The effect on the value of the direct current is greatest when the alternating current passes both through anodes and cathodes. The effect is least when the alternating current passes through the anodes only. In the former case, there is at first a diminution in the discharge potentials at both the electrodes but under conditions of very low current density produced by diminishing the voltage of the electrolytic current, the diminution in the anode discharge potential continues; but the cathode discharge potential remains constant or even increases. In the latter case, the discharge potential at the anode diminishes while that at the cathode increases from the very beginning. Similarly, by the passage of an alter-

nating current through the cathodes only, the discharge potential at that electrode only diminishes.

The results obtained with caustic soda solution are quite similar to those obtained with the sodium sulfate solution. Solutions of several other electrolytes were examined in the same way. The following relations seem to hold good generally: When the alternating current passes through cathodes, the cathode discharge potential diminishes, while there is a simultaneous increase in the anode discharge potential; when the alternating current passes through anodes, the reverse phenomenon happens; when the alternating current passes through both, the discharge potential at both the electrodes at first diminishes, but at very low current densities such is not always the case.

Conclusions.

From the above results it is quite obvious, that the alternating current need not be impressed on an electrolytic cell in conjugation with a direct current, in order to produce its marked effect on the discharge potentials at the electrodes. The alternating current acts primarily on the surfaces of the electrodes. Of course it is very difficult to suggest how it facilitates the liberation of the ions at the electrode surface, since we have not got very definite views as to the cause of the overvoltage phenomenon. It is not easy to imagine how an alternating current can destroy the super-saturation on the electrode surface, which is generally ascribed to be the cause of the overvoltage. The hypothesis that the alternating current somehow alters the nature of the electrode surface appears to be most reasonable. Ruer¹ has observed that platinum passes into solution when it is acted upon simultaneously by a direct and an alternating current. Under the conditions, in which the experiments described in this paper were carried out, such was not found to be the case. The weight of a platinum foil which had been used in the course of many of the above experiments remained absolutely constant.

Newbury, in his very recent work,² holds that the ions first penetrate into the interior of the electrodes and there get discharged. The molecules thus produced from the ions, have not, like the ions, got free passage through the material of the electrodes. They accumulate inside the electrode, and only at very high pressures they come out by boring tunnels through the electrode surface. Now any process which facilitates this disruption of the electrode surface, will diminish the discharge potential on the electrodes. An alternating current of considerable intensity could easily be imagined to brush aside all the mechanical resistances offered to the passage of the molecules out of the electrode surface. The liberation of the ions are thus greatly facilitated and hence the discharge potential sinks.

Summary of this Paper and the Previous Communication.³

1. When an alternating current of high frequency, about 30000 per minute, passes through a cell consisting of two platinum electrodes dipped in any electrolyte, the electrode potentials change, thus indicating that some chemical action at the electrode surface takes place in that short amount of time.

2. When an alternating current passes through a reversible voltaic cell, there is no change in the electrode potential. If, however, one of the electrodes consists of a metal covered with its insoluble salts, the alternating current has pronounced effect on that electrode.

¹ *Z. physik. Chem.*, **44**, 81 (1903).

² *J. Chem. Soc.*, 1419 (1914).

³ *THIS JOURNAL*, **36**, 2333 (1914).

3. A greater amount of current could be supplied by a cell with one reversible and another irreversible electrode, when an alternating current plays in the circuit.

4. In cells like $\text{Cd-ZnCl}_2\text{-Hg}$, $\text{Cd-ZnCl}_2\text{-Pt}$, etc., the E. M. F. of Hg or Pt electrode approaches the value of the zinc electrode on the passage of the alternating current.

5. In perfectly reversible electrolytic cells the alternating current has no action when impressed on the cell along with a direct current.

6. But if the electrolytic cell be irreversible, the alternating current greatly increases the current strength through the circuit.

7. This increase in current strength is due to the diminution in the back electromotive force of polarization.

8. This diminution in the discharge potential is also observed, in electrolytic cells consisting of two cathodes and two anodes, the alternating current playing between the anodes or the cathodes, but not passing through the whole circuit.

In conclusion, my best thanks are due to Professors P. C. Ray, and J. B. Bhaduri, for their interest and encouragement.

PROPERTIES OF SILVER IODIDE INTERPRETED IN RELATION TO RECENT THERMODYNAMIC CONCEPTIONS.

BY GRINNELL JONES AND MINER LOUIS HARTMANN.

Received February 8, 1915.

This paper presents the results of an experimental study of the most important thermodynamic properties of silver iodide, interpreted in the light of Richards' Theory of Compressible Atoms. These results have also furnished a quantitative test of the so-called Nernst Heat Theorem. They support the former theory, but not the latter.

The mathematical physicists who developed the kinetic theory of gases and liquids, in order to simplify the exceedingly complex mathematical analysis, were forced to assume that atoms are incompressible. Theodore William Richards¹ has, however, presented an array of facts and arguments which show that atoms and molecules are, in reality compressible, or, in other words, that the volume of the atoms is changeable, and dependent on the pressure exerted upon them, whether due to (1) external force, (2) the attraction between molecules of the same kind, which is manifested in cohesion, (3) the attraction of the atoms within the

¹ Professor Richards, in a Presidential Address for the American Chemical Society, "The Present Aspect of the Hypothesis of Compressible Atoms" (THIS JOURNAL, 36, 2417 (Dec., 1914)), gives a summary of the results obtained and a complete bibliography.

molecules, which is manifested in chemical affinity. Richards has shown also that the free space within the molecules has been commonly greatly overestimated, and that it is in all probability very small.

The old kinetic hypothesis, with its added assumption that the volume of the atom is unchangeable, accounts for the fact that the coefficient of expansion of all substances (with five known exceptions) is positive by the assumption that, with rising temperatures, the increased violence of the molecular collisions causes an increase in the free space between the molecules. A decrease in volume with rise in temperature, *i. e.*, a negative coefficient of expansion, is, however, entirely inexplicable on this conception of the nature of the atom. But the coefficient of expansion of silver iodide is negative.¹

The senior author of this paper has attempted to account for this negative coefficient of expansion of silver iodide by an extension of this hypothesis of atomic compressibility. It was suggested² that the change in volume which occurs when a solid is heated may be regarded as made up of at least three parts:

1. An increase in the intramolecular free space. This effect is, however, probably small, since the free space itself is probably very small.
2. An increase in the volume of the molecules due to a decrease in the cohesion.
3. A change in the volume of the atoms due to a change in the attractive force between the molecules.

In the case of silver iodide, whose volume decreases with rise in temperature, this hypothesis led to the inference that the attractive force increases with rise in temperature, and thereby produces an increased compression great enough to outweigh the effect of the first two influences.

Although the free energy of the reaction may not give a quantitative measure of the attractive force, since a part of the work done by the attractive force or chemical affinity may be expended in producing compression of the atoms, and thereby be stored up as potential energy within the compound and not be available for outside work, nevertheless, the free energy gives the best indication we have of the attractive force, and would be expected to have the same temperature coefficient as the attractive force itself.

A computation of the temperature coefficient of the free energy by the aid of the Helmholtz equation indicated that free energy and, therefore, also, affinity does really increase with rise in temperature, and thus the deduction from the hypothesis was confirmed.

¹ See Grinnell Jones, *THIS JOURNAL*, 31, 191 (1909) for a discussion of the experimental evidence for this statement, and for a brief discussion of the four other known cases of negative coefficient of expansion.

² Grinnell Jones, *Loc. cit.*

The data used in these earlier computations were collected from many sources, and the errors of all of them entered into the result.¹ It, therefore, seemed desirable to further test this explanation of the negative coefficient of expansion of silver iodide by direct measurement at two temperatures of the potential of an electrolytic cell, which, by its action, produces silver iodide from its elements. A detailed description of this experimental study is given in the following pages.

In order to be able to apply accurately corrections for osmotic work, and for the liquid junction potential, a knowledge of the mobilities and concentrations of all the ions in the solution, at the two temperatures involved, is required. The existing literature furnished this desired information at 25°² but for 0° it was necessary to determine the mobility of I^- and I_3^- ions, and the concentrations of each ion in the solutions of different strengths of potassium iodide saturated with iodine. The special investigation carried out for this purpose has recently been published.³

The Free Energy of Formation of Silver Iodide.

In order to measure the free energy of formation of silver iodide from silver and iodine, a reversible electrolytic cell was devised, which by its action forms silver iodide from the elements. The electromotive force of this cell (after making certain corrections to the observed potential) gives a measure of the tendency of the reaction to occur. The cell consisted of two halves, an iodine electrode and a silver-silver iodide electrode. The iodine electrode consisted of a platinum foil surrounded by solid iodine in a solution of potassium iodide. Some of the dissolved iodine formed the triiodide ion from the iodide ion. The silver-silver iodide electrode was made of a platinum wire covered with silver and silver iodide in a solution of potassium iodide of the same strength as that used around the iodine electrode.

The action may be considered as, first, the solution of the silver to form silver ion, but since the solution is already saturated with silver iodide, this silver ion is immediately precipitated as AgI by the excess of iodide ion in the solution. Simultaneously, an iodide ion is formed from the iodine at the platinum electrode. The result is a difference of potential, which gives a measure of the tendency of silver and iodine to combine. Proper corrections must be applied for the potential at the junction of the two halves of the cell and for the osmotic work caused by the different concentrations of iodide ions on the two sides.

Details of the Experiments.—The potentiometer used was of the usual

¹ The heat of formation of silver iodide given by Thomsen was obtained very indirectly by him by the combination of a large number of thermo-chemical data, so that this result seemed especially unreliable.

² Bray and MacKay, *THIS JOURNAL*, **32**, 914 (1910).

³ Jones and Hartmann, *Ibid.*, **37**, 241 (1915).

Poggendorf compensation type, constructed of standardized Leeds and Northrup decade resistance boxes. The Weston standard cell was tested by the Bureau of Standards. The potentiometer gave entire satisfaction. It was sensitive to 0.01 millivolt on cells of low internal resistance, such as two similar platinum electrodes about 1 cm. apart in a 0.1 *N* solution of potassium iodide saturated with iodine. When using our complete silver-silver iodide-iodine cell, which had a very much greater internal resistance, readings could still be made with ease and certainty to 0.1 millivolt.

The cells were deeply immersed in a mixture of finely cracked ice and distilled water contained in a large Dewar tube, which was carefully covered with many inches of cloth. The rate of gain of heat from the surroundings was so slow that no stirring was necessary to maintain the temperature accurately at 0°. For the measurements at 25°, the cells were placed in a large electrically controlled thermostat, which was carefully adjusted to 25.00°, by the aid of a thermometer which had been calibrated at the Bureau of Standards. Since a change of 1° in temperature changes the potential of the cell by only 0.18 millivolt, it was easy to control the temperature so accurately that no error need be feared from this source.

Preparation of Chemicals and Solutions.—Iodine and potassium iodide were prepared as described on pages 242, 243, of our first paper.¹

Silver oxide was prepared from pure silver nitrate recrystallized twice from conductivity water and drained centrifugally. Barium hydroxide, found by test to be free from halogens, was dissolved in water and allowed to stand until the barium carbonate had settled. The solution was then poured through a filter into a dilute solution of the purified silver nitrate. At the end a very slight excess of the silver nitrate remained, and the precipitate was washed free from barium and nitrate. The precipitate was not dried, but was kept under water for future use.

Silver iodide was made by precipitating pure silver nitrate with pure potassium iodide in dilute solution and washing free from potassium nitrate solution. This salt was also kept moist in the form of a paste, protected from decomposition due to light.

The solutions of potassium iodide and of potassium iodide saturated with iodine were prepared as described in the first paper. The solutions were ordinarily saturated with iodine at 25°, and since solid iodine is precipitated readily from such solutions on cooling, the solution would adjust its own iodine content at 0° when cooled. By trial it was found that this method gave the same results as when the iodine solution was saturated at 0°. In all cases, the platinum electrode was covered with solid iodine so that the solution must have been in equilibrium at the temperature under consideration.

¹ Jones and Hartmann, *Loc. cit.*

Preparation of the Silver-Silver Iodide Electrodes.—The problem of preparing constant and reproducible silver electrodes was solved only after many trials and failures, which need not be described in detail. After many less satisfactory procedures had been tried, the following was found to give very good electrodes: A platinum wire was sealed into a small glass tube so that outside connection could be made through mercury in the tube. The end of the platinum wire was wound into a small spiral and carefully cleaned. Silver was then electroplated onto the platinum from a solution of silver nitrate in potassium cyanide. A very small current—about 0.005 amperes for each electrode—was used for two hours. The electrode was then carefully washed free from cyanide, and dipped into a thick paste of silver oxide and water. The silver oxide on the wire was decomposed by slowly heating in a small electric oven at from 400° to 500°. It was found to be necessary to entirely decompose the silver oxide, or a different electromotive force was obtained. The silver oxide was applied several times and heated, until the spiral was filled with this finely divided but still coherent mass of silver.¹ The electrode was next made an anode in a dilute solution of potassium iodide, and thus coated with a very thin, coherent layer of silver iodide.² The current used in this operation was only 0.001 ampere, and the time was about two hours. The electrodes were allowed to stand in a fresh solution of potassium iodide, saturated with silver iodide, of the same strength as that in which they were to be used.

To show the reproducibility of this form of electrode, the following table will be sufficient. Electrodes 42, 44, 45 were made June 20th; 50 and 51 were made together June 27th; 63 and 64 were made July 1st. Nos. 42 and 51 had been in contact with potassium iodide containing free iodine. All had been used in various preliminary cells. These data were taken July 8th.

No. 64 against...	45	44	42	50	51	63
Difference.....	+0.00024	—0.00002	+0.00024	+0.00020	+0.00003	+0.00013 volt

Average difference from the mean 0.00009 volts.

Considering the diverse treatment of these electrodes before this measurement, the agreement is quite satisfactory.

The following table will show the variation of five of these electrodes, prepared at the same time and under identical conditions. The measurements were made with the electrodes dipping into a 0.1 *N* solution of potassium iodide saturated with silver iodide.

No. 61 against.....	62	63	64	65
Difference.....	—0.00002	—0.00001	0.00000	+0.00002 volt
Maximum difference between any pair.....				0.00004
Average difference from mean.....				0.00001

¹ This procedure was used by Lewis, *THIS JOURNAL*, 28, 166 (1906), for silver electrodes in silver nitrate solution.

² H. M. Goodwin, *Z. physik. Chem.*, 13, 630 (1894), used this procedure with good results.

The Iodine Electrodes.—The iodine electrodes were made after the manner described by Crotogino.¹ A piece of platinum foil about 1 cm. square was welded to a short platinum wire. This wire was sealed through the end of a glass tube, so that electrical connection could be made through a column of mercury. The platinum wire and foil were thoroughly cleaned with acids and heated white hot before use. They were then put into a potassium iodide solution saturated with iodine.

Five electrodes made in this way at different times and used in preliminary cells gave the following results, after standing in a 0.1 *N* solution of potassium iodide saturated with iodine:

No. 5 against.....	24	6	11	21
Difference.....	—0.00005	—0.00006	—0.00008	—0.00004 volt
Maximum difference between any pair.....	0.00008			
Average difference from the mean.....	0.00002			

Another set prepared and measured at a later time showed even better agreement. These electrodes were ignited in a gas flame to a white heat, and then allowed to stand short-circuited in a 0.1 *N* solution of potassium iodide saturated with iodine. The electrodes being close together, the internal resistance of the cell was low, and under these conditions our potentiometer was very sensitive, a change in the setting corresponding to 0.1 millivolt causing a deflection of 13 mm. on the scale of the galvanometer. It is evident that the iodine electrodes, if properly prepared and handled, need give us no anxiety.

Difference:						
0.00000	0.00000	0.00000	+0.00001	—0.000005	—0.000005	—0.000005 volt
Maximum difference of any pair.....	0.000015					
Average difference from mean.....	0.000003					

The Silver Iodide Cell.—The problem of preparing the electrodes having been solved, it now remained to find the best way to connect the two halves of the cell. The diffusion of iodine (or the triiodide ion) to the silver electrode must not occur for several days, the internal resistance of the cell must not become so great that our potentiometer would not be sensitive to 0.1 millivolt, and the conditions at the junction of the two liquids must approach, as nearly as possible, to the conditions which are assumed in the derivation of the equation, by which the potential at the liquid junction is calculated. The cells should be constant for a long time and reproducible. Cells were tried with the familiar double siphon connection, and also cells in which the connection was made in a U-tube filled with sand, but these cells were not as constant and reproducible as a cell of a much simpler construction in which the connection is made through

¹ Crotogino, *Z. anorg. Chem.*, **24**, 255 (1900).

a ground-glass stopper.¹ If the glass-grinding is very good, and the stopper firmly in place, the internal resistance is too great, and, therefore, the potentiometer not sufficiently sensitive, but by regrinding a very little with coarse carborundum, it was found to be possible to greatly increase sensitiveness of the potentiometer without causing unduly rapid diffusion of iodine to the silver electrode. Cells of this type were found to be appreciably more constant and reproducible than cells of any other type which were tried, and were used in all the final measurements. Planck, in the derivation of his formula for the potential at the boundary of two solutions, assumes that junction is sharp at the beginning, and that an intermediate layer of variable composition is produced by diffusion alone with *no mechanical mixing* of the solutions. This construction of the cell seems to realize this condition experimentally better than any other.

A sketch showing the construction of the type of cell which gave the most constant and reproducible results is shown in Fig. 1. The large outer tube was fitted with a rubber stopper through which the inner tube was inserted. Two holes were made in the stopper, large enough to allow the silver electrodes to be put through them, and a third small hole to allow equalization of air pressure was made. The silver electrodes were held in place by means of smaller rubber stoppers, which fitted into the holes in the main stopper. This arrangement allowed easy interchange of the electrodes without disturbing the cells. The inner tube had a ground-glass stopper at the end inside the cell. The upper end was provided with a paraffined cork stopper (which is not appreciably attacked by iodine vapors), which supported the iodine electrodes. The ground-glass stopper was held in place by a silver wire.

Fig. 1.

The large tube contained the potassium iodide solution saturated with silver iodide, and the inner tube contained the same solution saturated with iodine, and a large excess of solid iodine. In setting up the cell, the potassium iodide solution was first put in the outer tube and the saturated iodine solution, together with a large excess of solid iodine, put in the inner tube. The latter, with the large rubber stopper, was put into place as soon as the solution had wet the ground-glass joint, and the levels of the two solutions were quickly adjusted to avoid any difference of pressure. Then the iodine and silver electrodes were put in place and the whole apparatus made water proof with paraffin. It was then placed in the thermostat, and the potential measured.

¹ A. P. Laurie, *Z. physik. Chem.*, 64, 617 (1908), has used a liquid junction of this kind with success.

The potential of the cells when first set up was variable and not reproducible, but after allowing a few hours for the temperature and the condition at the boundary to adjust themselves, this uncertainty disappeared. Several of the cells containing 0.1 *N* potassium iodide solution were kept at constant temperature for a week, and the potential did not vary more than 0.0002 volt, and they were apparently in good condition when the measurements were stopped. The cells containing 0.05 *N* solution were not quite so constant. Their variation was, however, not over 0.0004 volt during several days. With a pair of each kind of electrodes in a cell, it was possible to obtain check readings on the electrodes, and these seldom varied more than 0.0002 volt. In the case of the iodine electrodes it was hardly ever possible to detect any difference at all, and in the later experiments only one of these electrodes was used.

Two strengths of potassium iodide were used, 0.1 *N* and 0.05 *N*. Measurements of the potential at 0° and 25° were made with both strengths of solution. Tables I, II, III, IV will show measurements of typical cells under the four conditions.

Many other cells of the same type were set up, but since they behaved in a very similar way, it does not seem necessary to record the observations in detail. The accepted potential judged from each of these cells alone is given below, which records all the cells which were not subject to known error and which remained constant for a reasonable length of time. A considerable number of cells were set up which for one reason or another

did not give constant and reproducible results. In some of these, the ground joint connecting the two halves of the cell was so imperfect that free iodine diffused through to the silver electrode too quickly. In still others, the ground joint was so perfect that the internal resistance of the cell was so great that accurate measurements were not possible. Cells of entirely different construction, with the familiar siphon connections, and cells in which the connection was made in a U-tube filled with sand were also tried, but were found to be less satisfactory and were abandoned. The accepted potentials of the cells which were constant and not influenced by known errors are given below.

The Liquid Junction Potential.—Planck,¹ by reasoning based on kinetic considerations, has deduced a general differential equation for the liquid junction potential between two solutions which differ in concentration by infinitesimal amounts. In order to integrate this equation between limits

¹ M. Planck, *Wied. Ann.*, 39, 161 (1890); 40, 561 (1890).

representing the composition of the two solutions around the electrodes, Planck has made the following assumptions:¹

1. The intermediate layer is produced by diffusion alone.
2. The mobility of any given ion is the same in both end solutions, and through the intermediate layer.
3. The simple van't Hoff Law $\pi = cRT$ holds.

Planck's general equation is complex, and somewhat troublesome to use, but for the special case when the total ion concentration is the same on both sides of the junction and all the ions are univalent, this reduces to the equation,²

$$E = \frac{RT}{F} \ln \frac{U_2 + V_1}{U_1 + V_2}$$

where U_1 is the sum of the products of concentration and mobility of all the cations present in solution 1. U_2 is the same sum for the other solution. V_1 and V_2 are the corresponding quantities for the anions.

It now remains to consider how closely our actual cells approach each of the assumptions involved in the derivation of the formula.

Planck's reasoning is based on the assumption that the intermediate layer is produced by diffusion alone, *i. e.*, the two solutions are first brought together with a sharp boundary, and then an intermediate layer is produced by diffusion without mechanical mixing. He concludes that the rate of diffusion at first will be very great, but after diffusion has proceeded for a short time, the rate of diffusion becomes so small that the amount of diffusion is negligible in the time required to measure the potential. He also concludes that the potential is independent of the thickness of the intermediate layer, but depends only on the composition of the end solutions. A junction within a ground-glass joint, such as we used, seems to us to meet this condition as perfectly as it is possible to do so experimentally. Some of our cells, after showing a variable potential for the first hour or two after they were set up, remained constant for a week, which is quite in accord with Planck's conclusions from his mathematical analysis of the problem.

Henderson³ has attacked the problem by a thermodynamic process of

¹ Planck restricts his treatment to solutions in which all the ions are univalent. The more general case, which is much more complex mathematically, has been treated by Plejél, *Z. physik. Chem.*, **72**, 1 (1910), and by K. R. Johnson, *Ann. Physik.*, **14**, 995 (1904), but does not concern us for the present purpose.

² In our cells the concentration of the ions is not identical on the two sides of the junction, owing to a slight change in volume, which occurs on dissolving iodine, and to a slightly different degree of dissociation of potassium iodide and triiodide. We have, therefore, carried out the calculations with Planck's general equation, and obtained a result which differs by only 0.01 millivolt from the result given by the simplified form.

³ P. Henderson. *Z. physik. Chem.*, **50**, 118 (1907); **63**, 325 (1908).

reasoning. He derives the same differential equation for the potential between two solutions differing in concentration by infinitesimal amounts that Planck obtained by kinetic reasoning. In order to integrate this equation, he assumes that the intermediate layer is formed, not by diffusion, but by the mechanical mixing of the end solutions. The last two assumptions made by Planck must also be made in Henderson's deduction. For the general case, the liquid potentials calculated by Henderson's equation and Planck's equation are appreciably different, but for the special case, met with in our cells, namely, the two end solutions containing a common cation (K^+) at the same concentration, and differing only in the anions (I^- in one case, and a mixture of I^- and I_3^- in the other), Henderson's equation reduces to a form which is identical with Planck's equation. This shows that if a little mixing occurred in making our junction, it would not affect the results.

It seems probable that as the I_3^- ion and I_2 and KI molecules diffuse into the pure potassium iodide solution, the reversible reaction $I^- + I_2 \rightleftharpoons I_3^-$ may cause some change in the concentrations of the ions, and thus in effect change the nature of the intermediate layer. Since we do not know the relative rate of diffusion of the triiodide ion (I_3^-) and molecular iodine (I_2), it is not possible to determine the influence of this on the intermediate layer. It is, therefore, reassuring that the Planck and Henderson equations, which assume quite different intermediate layers, give identical results for our special case.

The second assumption is not strictly met by our cells, since there is a slight difference in the viscosity of the two solutions, but we have convinced ourselves by suitable computations that this effect is so small that it may safely be neglected.

The third assumption is not met exactly even by dilute solutions. The "activity," to use the term proposed by G. N. Lewis, is not strictly proportional to the concentration. In the light of our present knowledge, however, it does not seem feasible to avoid the error inherent in this assumption.¹

The values for the mobilities and concentrations of the ions used in this computation at 0° have been determined by a special investigation, carried out for the purpose, and recently published.² The corresponding data for 25° are based upon the data of Bray and MacKay,³ corrected for the effect of viscosity.²

¹ Experiments are under way, which, it is hoped, will throw more light on this question. But since this is a large problem in itself, which must require some time for completion, and since the outcome cannot affect the main conclusions of this paper, it has not seemed wise to postpone publication of the results already obtained, pending the outcome of this further study.

The Osmotic Work Correction.—The measured potential of the silver iodide cell must be further corrected on account of the osmotic work. In the reaction in the cell, iodide ion is produced (at the iodine electrode) in a solution of one concentration with respect to this ion, while a corresponding amount of iodide ion is removed (as silver iodide) at the other electrode from a solution almost twice as concentrated in iodide ion. This involves some osmotic work, which is included in the measured potential of the cell, and must be taken into consideration.

The familiar Nernst concentration cell equation is the most accurate method, according to our present knowledge, of calculating this potential.

$$(E_2 - E_1) = RT/F \ln C'_I / C''_I$$

C'_I = Concentration of iodide ion in potassium iodide solution.

C''_I = Concentration of iodide ion in same solution saturated with iodine.

This equation is obtained by the integration of a differential equation, which is derived thermodynamically and is doubtless accurate, but in order to integrate the equation in the form given, it is necessary to assume that the simple van't Hoff law holds. This assumption probably is not fulfilled exactly by our solutions, so that this correction may not be quite accurate. This potential due to osmotic work is in the same direction as the measured potential, and hence should be subtracted from the measured potential of the cell.

The potentials of the cell under the four conditions are given in Table V. In this table are also given the corrections which must be applied to the measured potentials, and the final corrected potentials, which represent the tendency of iodine and silver to combine with each other.

TABLE V.

	At 0°.		At 25°.

Free energy (A) kilogram calories...	15.72	15.69	15.81	15.80

Temperature coefficient of electromotive force from measurements with 0.1 N solution = $(0.6852 - 0.6812)/25 = +0.000160$ volt per degree, equivalent to 15.5 mayers or 3.7 calories per degree.

Temperature coefficient of electromotive force from measurements with 0.05 N solution = $(0.6847 - 0.6798)/25 = +0.000196$ volt per degree, equivalent to 18.9 mayers or 4.5 calories per degree.

The difference between the results with 0.1 N and 0.05 N solutions is probably due to the fact that the activity of the ions is not proportional to the concentration, especially in the stronger solution. This subject

has been discussed in considerable detail by Bray and MacKay, whose conclusion is, "It is evident that, no matter what assumption is made, one or more of the substances involved will show marked deviations from the law of the ideal solution that activity and concentration are equal." Since these deviations are undoubtedly less in the more dilute solution, we regard the result obtained with the 0.05 *N* solution as the more reliable, although the result with the stronger solution furnishes a valuable confirmation.

These results show conclusively that the temperature coefficient of the free energy of formation of silver iodide is positive, and thus support the analysis of the coefficients of expansion based on Richards' hypothesis of compressible atoms, and furnish us with a reasonable explanation of this almost unique property of silver iodide.

Free Energy, Total Energy, and Heat Capacity.

His conception of the compressible atom led Richards¹ to some new fundamental ideas regarding the relationship between the attracting energy or chemical energy, the free energy or power of producing outside work, and the heat evolved during a reaction, when it proceeds isothermally and under such conditions that no outside work is done.

"When the heat capacity of a system does not change during a reaction, and concentration influences are balanced, the free-energy and total-energy changes of the reaction are equal and unchangeable with the temperature, and each may be supposed to represent the total 'attracting energy'—a term which covers gravitational and electrical attraction as well as purely chemical attraction."

Richards pointed out that the compression which usually occurs during a chemical reaction must diminish the heat capacity by restricting the vibrations, so that the heat present in the factors before the reaction is more than sufficient to raise the temperature of the products from absolute zero to the temperature of the reaction. Therefore, the heat evolved during the reaction, as measured in the usual way in a calorimeter, is greater than the heat produced from the chemical energy of the reaction. Or, in other words, the "Wärmetönung" is greater than the chemical energy. In such a case, the free energy is less than the chemical energy, since a part of the chemical energy is expended in producing the compression of the atoms, and is not available for outside work. Since $dU/dT = C_F - C_P$ (molecular heat capacity of factors minus molecular heat capacity of products), and C_F is greater than C_P , dU/dT will be positive. Richards reasoned that in such a case dA/dT is negative, and was able to support this conclusion by experimental evidence. The possibility of the converse case is also clearly indicated by Richards, although such cases are much rarer.

One of these converse cases is silver iodide, a most interesting substance

¹ *Proc. Amer. Acad.*, 38, 293 (1902).

from the standpoint of this hypothesis, because it has several exceptional properties, and one which is almost unique.¹ During the formation of silver iodide from its elements, there is an increase in volume of nearly 15% of the whole, in contrast to most salts, which show a decrease in volume during formation.² The molecular heat capacity of silver iodide is greater than the sum of the heat capacities of silver and iodine,³ which is also unusual, but is related to the increase in volume, as already pointed out in the discussion of the more common converse case. By reference to Table V, it will be seen that the free energy of formation of silver iodide (A) is 66.1 kilojoules at 25°. It is easily possible to compute by the Helmholtz equation from the data presented in Table V that the heat evolved (U) is 61.0 kilojoules. A is, therefore, greater than U. dU/dT is negative and dA/dT is positive, and the coefficient of expansion is negative. These facts in regard to silver iodide thus confirm conclusions which Richards drew from the hypothesis of compressible atoms in a complete and remarkable way. The case is all the more noteworthy, because the relations are just the converse of those usually met with, but it is nevertheless entirely consistent.

In order that a quantitative formulation of these relationships may be subjected to a rigid test in many cases, it is necessary to know the atomic and molecular heat capacities of both factors and products of the reactions under consideration from absolute zero up to the working temperatures. Richards and Jackson⁴ began the collection of the data on specific heats of solids down to liquid air temperatures, and in 1910 published results on twenty-six elements. These results showed that the specific heats are very much less at low temperatures than at room temperature.

Richards first published these new fundamental ideas in regard to the "Significance of Changing Atomic Volume" in 1902. Nernst⁵ attempted, in 1906, to give these ideas a mathematical formulation. But in doing this he made two assumptions which require experimental proof. These assumptions will be discussed in detail after Nernst's mathematical formulation has been followed to the point where these assumptions are necessary for further progress.

In his early papers, Nernst expressed the atomic or molecular heat capacities of solids as a function of temperature in the form of a rapidly

41.38 — (10.28 + 25.73) = 5.37 cc. increase in volume during formation of salt.

³ A discussion of the experimental evidence for this statement will be found on a later page.

⁴ Richards and Jackson, *Z. physik. Chem.*, 70, 414 (1910).

⁵ Nernst, *Göttinger Nachrichten*, 1906, 1.

convergent polynomial series in powers of T , but this expression was later abandoned in favor of Einstein's specific heat formula, and this in turn was superseded by a new specific heat formula proposed by Nernst and Lindemann.

In 1907, Einstein¹ had derived the following expression for the atomic or molecular heat capacity of solids at constant volume as a function of the absolute temperature and the "vibration frequency" of the atoms (or electrons within the atoms).

$$C_v = 3R \sum \frac{(\beta \nu / T)^2 e^{\beta \nu T}}{(e^{\beta \nu T} - 1)^2}$$

C_v = atomic (or molecular) heat capacity at constant volume.

R = gas constant.

e = base of natural logarithms.

T = absolute temperature.

β = 4.86×10^{-11} , a universal constant, whose numerical value was deduced by Planck from a study of radiation phenomena.

ν = vibration frequency theoretically, but in practice is usually selected empirically to make the formula fit the data as well as possible.

Σ = the summation sign which indicates that summation is to be extended over the vibrations of all the frequencies which are actually occurring.

This formula was deduced by applying the Quanten Hypothesis, which Planck formulated for the ether vibrations, to the vibrations of solids. The assumption is made that the atoms of a solid cannot take up heat continuously,² but only in units or "quanta," and that the magnitude of the units is proportional to the vibration frequency.

The heat capacity at constant volume (C_v) cannot, however, be determined experimentally. The heat capacity at constant pressure C_p , which can be experimentally determined, and is desired in the development of the theory, can, however, be computed from C_v by the following well known thermodynamic formula.

$$C_p = C_v + 9 \alpha^2 VT/K.$$

α = cubic coefficient of expansion (thermal).

K = coefficient of compressibility.

V = molecular volume.

Unfortunately we have little exact knowledge of α and K as functions of the temperature. Nernst and his co-workers replace the last term by $\alpha T^{3/4}$ (where α is constant for any substance), pointing out that this accords with what we know in regard to the influence of temperature on α and K , and that this last term is small in comparison to the first term.

¹ Einstein, *Ann. Phys.*, [4] 23, 180 (1907).

² The word "continuously" is used in its mathematical sense.

This formula was found to be in agreement with the early results obtained in Nernst's laboratory by Nernst, Eucken, Pollitzer, Koref, and Lindemann, which extended to liquid air temperatures only.

When, however, the measurements were extended down to the temperature of liquid hydrogen, it was found that the experimental results were unmistakably higher than the results computed from the Einstein formula. Nernst and Lindemann¹ then proposed a modified formula

$$C_p = \frac{3}{2}R \sum \left\{ \frac{(\beta\nu/T)^2 e^{\beta\nu/T}}{(e^{\beta\nu/T} - 1)^2} + \frac{(\beta\nu/2T)^2 e^{\beta\nu/2T}}{(e^{\beta\nu/2T} - 1)^2} \right\} + \alpha T^{1/2}.$$

which was found to fit the data very much better down to liquid hydrogen temperatures. This formula was originally found empirically, but Nernst and Lindemann point out that, if the assumption is made that the potential energy of the atom due to its separation from its position of rest is taken up in quanta which are one-half as great as the quanta of the kinetic energy, then this formula may be derived by reasoning very similar to that of Einstein. In the case of the metals it was only necessary to assume a single value for ν , and in the case of simple salts containing two elements, it was only necessary to assume two values of ν corresponding to the two kinds of atoms. Two values of ν are assumed in the case of sulfur and graphite, but only one for diamond. Three values of ν are assumed in the case of silica and mercurous sulfate.

According to this formula, the heat capacities approach zero as their limit, as the temperature approaches absolute zero. This remarkable result has been experimentally confirmed by Nernst² and Lindemann in the case of the diamond. According to this formula, C_p approaches $3R$ as its limit, as the temperature is raised. This is in entire accord with the conclusions reached previously by G. N. Lewis,³ that the deviations from Dulong and Petit's Law are due partly to the second term involving the heat absorbed during thermal expansion, and in the case of a few elements to the necessity of reaching high temperatures, before Dulong and Petit's Law holds. Moreover, we have convinced ourselves by suitable calculations, that the formula can be made to fit, at least approximately, the data of Richards and Jackson, and Griffiths and Griffiths.⁴

In the case of three salts (KCl, KBr and NaCl) the value of the vibration frequency may be computed from the measurements of the wave lengths of the residual rays (Reststrahlen) by Rubens and Hollnagel.⁵

¹ Nernst and Lindemann, *Sitzb. Akad. Wiss. Berl.*, 1911, 494; *Z. Elektrochem.*, 17, 817 (1911).

³ *THIS JOURNAL*, 29, 1165 (1907).

⁴ *Phil. Trans.*, (A) 213, 119 (1913); *Proc. Roy. Soc. London*, (A) 90, 557 (1914).

⁵ *Sitzb. Akad. Wiss. Berl.*, 1910, 26; *Vdlg. d. D. phys. Ges.*, 12, 83 (1910).

Since the other quantities in the formula are all known for these salts, it has been possible to compute the heat capacity without selecting any quantity empirically to fit the data. The calculated results accord with the observed within 1%, which must certainly be regarded as a great triumph for the formula.

The assumption of a single vibration frequency seems *a priori* very improbable in view of the fact that solids show a continuous spectrum. Three attempts to derive a specific heat formula with the aid of the Quanta theory, without using the simplifying assumption that one or two vibration frequencies only are involved, have been published by Debye,¹ Born and von Karman,² and von Juptner.³ Von Juptner's formula leads to negative values for C_v in certain intervals of temperature, and may, therefore, be dismissed at once. Debye's formula and Born and von Karman's formula both give specific heat curves which are very similar to those given by the Nernst-Lindemann formula. All of them give C_v rather than C_p .

The formula of Debye is

$$C_v = 3R \left\{ \frac{4}{5} \frac{\pi^4}{\beta\nu} \left(\frac{T}{\beta\nu} \right)^3 - \frac{3}{e^{\beta\nu/T} - 1} \right. \\ \left. - 12 \beta\nu/T \sum_{n=1}^{\infty} e^{-n\beta\nu/T} \left(\frac{1}{n\beta\nu/T} + \frac{3}{n^2 (\beta\nu/T)^2} + \frac{6}{n^3 (\beta\nu/T)^3} + \frac{6}{n^4 (\beta\nu/T)^4} \right) \right\}.$$

This formula was shown by Debye to give results almost identical with those of the Nernst-Lindemann formula, except at very low temperatures, where it gives higher results. Nernst and Lindemann have carried out the laborious computations necessary to compare the results obtained with this formula and with their own formula with experimental results in the cases of aluminum, copper, silver, diamond, potassium chloride, and sodium chloride. They conclude that the new Debye formula is slightly better than their own. However, a careful examination of the results of these computations shows that the advantage of the Debye formula is very small, if it exists at all. The two formulas agree with each other much better than either agrees with the experimental results, and each has the advantage in about one-half of the cases, and they, therefore, may be regarded as practically identical, until data are available which are accurate enough to make possible a choice between the two formulas.

In the following mathematical development of the theory and the computations based thereon, we have used the Nernst-Lindemann formula in preference to the Debye because of its much simpler mathematical form,

¹ *Ann. Physik.*, **39**, 789 (1912).

² *Physik. Z.*, **13**, 308 (1912).

³ *Z. Elektrochem.* **19**, 711 (1913).

and because it is the form used by Nernst and his students to test the theory.¹

So many doubtful assumptions are involved in the derivation of the Nernst-Lindemann formula that it seems to us best to regard it simply as an empirical formula, in which the numerical value of a and one or more values of $\beta\nu$ are selected arbitrarily to fit the data as well as possible. There can be no doubt that a polynomial series in powers of T would require many more empirical constants to make it fit the data as well.

By Kirchhoff's Law

$$\frac{dU}{dT} = C_F - C_P = \frac{3}{2}R \sum_{F-P} \left\{ \frac{(\beta\nu/T)^2 e^{\beta\nu/T}}{(e^{\beta\nu/T} - 1)^2} + \frac{(\beta\nu/2T)^2 e^{\beta\nu/2T}}{(e^{\beta\nu/2T} - 1)^2} \right\} + \sum_{F-P} aT^{3/2} \quad (1)$$

U is the heat evolved when the reaction proceeds isothermally in such a way that no external work is done. If only solids are involved in the reaction, and the pressure is not over one atmosphere, the external work due to changes in volume during the reaction may be neglected.

C_F and C_P are the heat capacities of the factors and the products of the reaction, respectively, at constant pressure.

Integrating:

$$U = U_0 + \frac{3}{2}R \sum_{F-P} \left\{ \frac{\beta\nu}{e^{\beta\nu/T} - 1} + \frac{\beta\nu}{2(e^{\beta\nu/2T} - 1)} \right\} + \sum_{F-P} \frac{2}{5}aT^{5/2} \quad (2)$$

U_0 is an integration constant, but if we place $T = 0$ in this expression, all other terms vanish, and it is, therefore, the heat evolved at absolute zero.

$$A - U = T dA/dT \quad (3)$$

where A is the maximum amount of external work which can be done by the chemical reaction. In the case under consideration, this work is all electrical work.

$$\frac{AdT - TdA}{T^2} = \frac{UdT}{T^2} \quad (4)$$

$$-d\left(\frac{A}{T}\right) = \frac{UdT}{T^2} \quad (5)$$

Before we can integrate, it is necessary to express U as a function of T by means of Equation 2.

$$-d\left(\frac{A}{T}\right) = \frac{U_0 dT}{T^2} + \frac{3}{2}R \sum_{F-P} \left\{ \frac{\beta\nu dT}{T^2(e^{\beta\nu/T} - 1)} + \frac{\beta\nu dT}{2T^2(e^{\beta\nu/2T} - 1)} \right\} + \sum_{F-P} \frac{2}{5}aT^{1/2}dT. \quad (6)$$

¹ Nernst has published the calculations with the Debye formula in one case only as far as we have been able to find. Fortunately for our purposes, the case chosen was the formation of silver iodide, in which we are especially interested. This calculation showed that the results for A and U are practically identical, using either the Nernst-Lindemann or the Debye formula. Nernst says "bei der Berechnung chemischer Affinität von kondensierten Systemen sind wohl bei allen Temperaturen (vielleicht ganz extreme Fälle ausgenommen) die Differenzen praktisch belanglos." *Sitzb. Akad. Wiss. Berlin* 1912, 117A

Integrating

$$-\frac{A}{T} = -\frac{U_0}{T} - I + \frac{3}{2}R \sum_{F-P} \left\{ \frac{\beta\nu}{T} - \ln(e^{\beta\nu/T} - 1) + \frac{\beta\nu}{2T} - \ln(e^{\beta\nu/2T} - 1) \right\} + \sum_{F-P} \frac{4}{15}aT^{3/2}. \quad (7)$$

$$A = U_0 + IT - \frac{3}{2}R \sum_{F-P} \left\{ \frac{3}{2}\beta\nu - T \ln(e^{\beta\nu/T} - 1) - T \ln(e^{\beta\nu/2T} - 1) \right\} - \sum_{F-P} \frac{4}{15}aT^{3/2} \quad (8)$$

Differentiating

$$\frac{dA}{dT} = +I - \frac{3}{2}R \sum_{F-P} \left\{ \frac{3}{2} \frac{\beta\nu}{T} - \ln(e^{\beta\nu/T} - 1) + \frac{\beta\nu/T}{e^{\beta\nu/T} - 1} - \ln(e^{\beta\nu/2T} - 1) + \frac{\beta\nu/2T}{e^{\beta\nu/2T} - 1} \right\} - \sum_{F-P} \frac{2}{3}aT^{1/2}. \quad (9)$$

I is an integration constant, which is thermodynamically indeterminate, and whose physical significance is by no means clear.¹ The presence of this constant in the equation for A and dA/dT makes it impossible to compute the free energy from data on specific heats and thermochemical data alone, but makes it necessary to determine A experimentally for some one temperature at least. This very greatly restricts the usefulness of the equation, because there are many reactions for which the thermochemical and specific data are available or readily obtainable experimentally, whose free energy cannot be determined by any means known to us at the present time.

The two fundamental assumptions made by Nernst, and which constitute the essence of the so-called Nernst Heat Theorem, are

$$\lim_{T \rightarrow 0} \left(\frac{dU}{dT} \right) = 0$$

and

$$\lim_{T \rightarrow 0} \left(\frac{dA}{dT} \right) = 0.$$

These assumptions apply only to reactions taking place in "condensed systems," i. e., in systems involving only solids and liquids, but no gases or solutions. The possible truth of these relationships was clearly foreshadowed by Richards,² but at the time very few data were available on specific heats at low temperatures so that a rigid test of these ideas was impossible. Does the new evidence made available since 1902 en-

¹ Lewis, THIS JOURNAL, 35, 29 (1913). Haber "Thermodynamics of Technical Gas Reactions" translation by A. B. Lamb, p. 41ff.

² See especially *Proc. Amer. Acad.*, 38, 302 (1902), and *Z. physik. Chem.*, 42, 138 (1902).

able us to advance beyond the conservative position taken by Richards at that time?

If the specific heats of all solids approach the same limit zero, as we approach absolute zero, as required by the Nernst-Lindemann formula, and as found experimentally in the case of the diamond, then the first assumption follows as a necessary consequence by Kirchhoff's Law.

If in the expression for dA/dT we place $T = 0$, everything vanishes except the term $+I$, leaving $\lim_{T=0} \left(\frac{dA}{dT} \right) = I$.

Therefore, if we accept the Nernst-Lindemann¹ specific heat formula as valid down to absolute zero, then a mathematically equivalent way of stating the second of Nernst's assumptions for condensed systems is $I = 0$. This is very important, if it can be proved, because it makes it possible to calculate, from thermal data alone, the free energy of any reaction, and hence the equilibrium constant of the reaction, and the electromotive force of a galvanic cell. This assumption has been referred to by some of Nernst's disciples² as the Third Law of Thermodynamics. But as the First and Second Laws of Thermodynamics were established only by extensive experimental evidence, similar evidence will be required to justify this title.

Nernst's second assumption may be tested by the data presented in this paper, measurements of the heat capacities of silver, iodine, and silver iodide made by Nernst³ being accepted.

The following table shows the values of β_v and a , which have been selected by Nernst in order to make the results computed with the Nernst-Lindemann formula agree as well as possible with the experimental results.

	β_v	a
Ag.....	221	0.000048
I.....	98	0.000100
AgI.....	220 and 70	0.00020

In the case of silver, the calculated and observed results agree within about 1%. These results are also confirmed, at least down to liquid air temperatures, by the results of Richards and Jackson, and Griffiths and Griffiths within 1%. The results on silver iodide agree with those computed from

¹ The same would be true for any other specific heat formula, which would yield a function in the equation for dA/dT which vanishes when $T = 0$. This would be true for the Debye formula, or for a formula having the form of a convergent polynomial series $C_p = a + bT + cT^2 + \dots$, in which the first term a is zero in accordance with Nernst's first assumption.

² For example, Karl Jellinek, "Physikalische Chemie der homogenen und heterogenen Gasreaktionen unter besonderer Berücksichtigung der Strahlungs- und Quantenlehre sowie des Nernstschen Theorems." (Book published by Hirzel, Leipzig, 1913, p. 478.)

³ *Ann. Physik.*, 36, 395 (1911).

the formula nearly as well. Recently a new series of results on silver iodide has been published by Nernst and Schwes, ¹ using a much modified apparatus. By plotting the new results and the old results (C_p against T) it becomes evident that the new and the old results do not agree well with each other, and moreover the curve depicting the new results has an abnormal and unusual shape. ² Moreover no new results on iodine and silver obtained by the new method are available, and it, therefore, seems best to use the old results in this computation. In the case of iodine, the agreement is not so close, discrepancies of $\pm 3\%$ being common, and at the lowest temperature (28.3°A), the discrepancy is 6% .

Estreicher and Staniewski ³ have measured the average specific heat of iodine from -190° to $+17^\circ$ and from -80° to $+17^\circ$. Their result is 2% higher than that computed from the Nernst-Lindemann equation using the above values of $\beta\nu$ and a .

A plot of these results shows very clearly that the heat capacity of silver iodide exceeds the sum of the heat capacities of silver and iodine.

The best way to test the question whether or not $I = 0$ is to substitute the above values of $\beta\nu$ and a in Equation 9, which gives the following results:

$$\text{at } 0^\circ \quad dA/dT = I + 2.18 \text{ calories per degree;}$$

$$\text{at } 25^\circ \quad dA/dT = I + 2.20 \text{ calories per degree.}$$

But the value found experimentally with 0.05 N KI solution was

$$dA/dT = 4.52 \text{ calories per degree}$$

$$\text{hence } I = 4.52 - 2.19 = +2.33 \text{ calories per degree.}$$

This may be checked in another way by using Equation 8, which gives the following results:

$$A_{273} = U_0 + I \times 273 + 510 \text{ calories.}$$

$$A_{298} = U_0 + I \times 298 + 565 \text{ calories.}$$

But according to our measurements with 0.05 N solution

$$A_{273} = 15687 \text{ calories.}$$

$$A_{298} = 15800 \text{ calories.}$$

Then solving these two equations simultaneously, we obtain $I = 2.33$ and $U_0 = 14541$, and since $273 \times 2.33 = 636$, the term IT , which Nernst assumes to be zero and discards, is greater than the sum of all the terms involving the $\beta\nu$ and a of the Nernst-Lindemann specific heat formula.

In an exactly similar way we may carry out the computations with our results obtained in 0.1 N solution, for which the experimental value of

¹ Sitzb. Akad. Wiss. Berlin, 1913, 367.

² The increase in C_p with the temperature is very great up to 85.2°A , and then becomes unusually small, giving a sharp bend in the curve which is abnormal. The curve for the old results has the shape commonly found in such curves.
